ABSTRACT

Abstract—Neurological and neurodevelopmental disorders, such as Autism Spectrum Disorder (ASD), Parkinson's disease, Alzheimer's disease, and depression, pose significant challenges to early diagnosis and intervention. To address this, we propose an AI-driven desktop application that leverages machine learning (ML) and deep learning (DL) for automated detection and monitoring of these conditions through four key components. The first component employs a conversational AI chatbot that analyzes linguistic patterns and sentiment in user interactions to assess depression levels, achieving an accuracy of 94%. The second component utilizes real-time facial image analysis via a webcam to detect early ASD indicators, with a model accuracy of 91%. The third component enhances ASD detection by integrating a structured 10-question questionnaire that evaluates behavioral and cognitive responses, achieving 96% accuracy. The fourth component processes brain imaging data and handwriting patterns to identify neurological biomarkers associated with Alzheimer's and Parkinson's disease, achieving respective accuracies of 93% and 95%. By integrating these AI-powered assessments, the system streamlines traditional screening methods, reducing dependency on manual evaluations while enhancing diagnostic precision. This innovative approach not only empowers healthcare professionals with data-driven insights but also fosters early intervention and personalized monitoring, paving the way for more efficient and accessible neurological disorder management.

Keywords— Autism Spectrum Disorder, Parkinson's disease, Alzheimer's disease, depression, deep learning, facial analysis, chatbot, questionnaire-based assessment, neurodegenerative disorders, clinical decision support.

ACKNOWLEDGEMENT

We would like to express our sincere gratitude to all those who supported and guided us throughout the successful completion of our fourth-year research project. First and foremost, we extend our heartfelt appreciation to our research supervisor, Ms. Wishalya Tissera, for her continuous encouragement, expert guidance, and valuable insights, which were instrumental in shaping the direction of our study. We are also thankful to our co-supervisor, Dr. Kapila Dissanayaka, for providing us with technical expertise and constructive feedback that greatly enhanced the quality of our work. Our sincere thanks go to the CDAP panel for their thoughtful suggestions and guidance, which helped us improve various aspects of the research. We also acknowledge the contributions of our external supervisor, Dr. Anuradha Baminiwatta, for facilitating coordination and offering crucial information during the initial stages of the project. We are especially grateful to our research project leader, Mr. Dilshan G.A.M, for his leadership and continuous support, and to all group members for their collective efforts in material collection, data analysis, and development work. We would also like to thank our faculty and department for providing the necessary resources, facilities, and academic support throughout the duration of the project. If applicable, we gratefully acknowledge the assistance of any external organizations or funding bodies that contributed to our research. Lastly, we appreciate the constant encouragement and emotional support from our families and friends, whose motivation was a great source of strength during this journey.

1.0 INTRODUCTION

Neurological and neurodevelopmental disorders, such as Autism Spectrum Disorder (ASD), Parkinson's disease, Alzheimer's disease, and depression, affect millions of individuals worldwide, often leading to significant cognitive, behavioral, and motor impairments. Early diagnosis and continuous monitoring are crucial in improving patient outcomes and assisting healthcare professionals in providing timely interventions. However, traditional clinical methods rely heavily on subjective assessments, making the diagnostic process time-consuming, resource-intensive, and sometimes inconsistent. To address these limitations, we propose an AI-driven desktop application that utilizes machine learning (ML) and deep learning (DL) techniques to automate the detection and monitoring of these disorders, offering a more efficient, accessible, and data-driven approach to neurological healthcare.

Depression is a widely prevalent mental health condition that often remains undiagnosed due to stigma, lack of awareness, and limited access to mental health professionals. To tackle this challenge, our system incorporates a conversational AI chatbot designed to engage users in structured interactions and assess their depression levels based on linguistic and textual patterns. By analyzing sentiment, tone, and conversational flow, the chatbot detects potential indicators of depression and provides real-time feedback. This AI-based approach eliminates the need for in-person clinical evaluations while enabling individuals to receive early mental health support in a non-intrusive and accessible manner. The integration of natural language processing (NLP) techniques ensures high accuracy in detecting depressive symptoms, making this an effective tool for mental health screening and intervention.

Alzheimer's disease is a progressive neurodegenerative disorder that affects memory, cognitive function, and daily life activities. Given its increasing prevalence, early detection is vital for slowing disease progression and improving patient management. Our system integrates a brain imaging analysis module powered by deep learning models to detect early biomarkers of Alzheimer's disease. By analyzing patterns in MRI and CT scan data, the system identifies structural abnormalities and early signs of neurodegeneration. This AI-assisted diagnostic tool reduces dependence on traditional clinical evaluations and makes early screening more accessible, particularly in regions with limited access to neurological specialists. The automated analysis of medical imaging data not only enhances diagnostic accuracy but also aids in tracking disease progression over time.

Parkinson's disease primarily affects motor function, leading to tremors, stiffness, and slowed movement. One of the earliest indicators of the disease is a decline in fine motor skills, which can be observed in handwriting patterns. Our system incorporates a writing pad-based module that enables patients to perform specific handwriting tasks, such as drawing spirals, writing sentences, or tracing predefined shapes. The system captures key handwriting characteristics, including stroke smoothness, writing speed, letter size consistency, and spatial alignment. By analyzing these features, the system identifies signs of motor impairments associated with Parkinson's disease. This non-invasive approach allows for early diagnosis and continuous

monitoring of disease progression, helping clinicians assess motor deterioration over time and provide timely intervention.

Hypomimia, or reduced facial expressiveness, is a common symptom of Parkinson's disease that often goes unnoticed in routine clinical assessments. To enhance symptom tracking, our system integrates a real-time facial recognition module that captures and analyzes facial expressions, along with voice and handwriting samples, to provide a more comprehensive evaluation of Parkinson's-related motor impairments. Patients are guided through a series of tasks, including facial exercises (such as smiling, raising eyebrows, and opening and closing their mouths), speaking predefined sentences into a microphone, and performing handwriting tasks on a digital writing pad. The system records facial muscle activation, voice modulation, and handwriting characteristics, such as stroke smoothness, letter size consistency, and writing speed. By analyzing these multimodal inputs, the system can identify subtle impairments that indicate disease progression. Additionally, it stores historical data, allowing healthcare professionals to compare current results with previous assessments to track changes over time. This integrated approach provides a more objective and data-driven method for monitoring Parkinson's disease, enabling more accurate diagnosis and personalized treatment planning.

Parkinson's disease, Alzheimer's disease, and depression affect millions of individuals worldwide, often leading to significant cognitive, behavioral, and motor impairments. Early diagnosis and continuous monitoring are crucial in improving patient outcomes and assisting healthcare professionals in providing timely interventions. However, traditional clinical methods rely heavily on subjective assessments, making the diagnostic process time-consuming, resource-intensive, and sometimes inconsistent. To address these limitations, we propose an AI-driven desktop application that utilizes machine learning (ML) and deep learning (DL) techniques to automate the detection and monitoring of these disorders, offering a more efficient, accessible, and data-driven approach to neurological healthcare.

Depression is a widely prevalent mental health condition that often remains undiagnosed due to stigma, lack of awareness, and limited access to mental health professionals. This AI-based approach eliminates the need for in-person clinical evaluations while enabling individuals to receive early mental health support in a non-intrusive and accessible manner. The integration of natural language processing (NLP) techniques ensures high accuracy in detecting depressive symptoms, making this an effective tool for mental health screening and intervention.

Alzheimer's disease is a progressive neurodegenerative disorder that affects memory, cognitive function, and daily life activities. Given its increasing prevalence, early detection is vital for slowing disease progression and improving patient management. Our system integrates a brain imaging analysis module powered by deep learning models to detect early biomarkers of Alzheimer's disease. By analyzing patterns in MRI and CT scan data, the

system identifies structural abnormalities and early signs of neurodegeneration. This AI-assisted diagnostic tool reduces dependence on traditional clinical evaluations and makes early screening more accessible, particularly in regions with limited access to neurological specialists. The automated analysis of medical imaging data not only enhances diagnostic accuracy but also aids in tracking disease progression over time.

Parkinson's disease primarily affects motor function, leading to tremors, stiffness, and slowed movement. One of the earliest indicators of the disease is a decline in fine motor skills, which can be observed in handwriting patterns. Our system incorporates a writing pad-based module that enables patients to perform specific handwriting tasks, such as drawing spirals, writing sentences, or tracing predefined shapes. The system captures key handwriting characteristics, including stroke smoothness, writing speed, letter size consistency, and spatial alignment. By analyzing these features, the system identifies signs of motor impairments associated with Parkinson's disease. This non-invasive approach allows for early diagnosis and continuous monitoring of disease progression, helping clinicians assess motor deterioration over time and provide timely intervention.

Hypomimia, or reduced facial expressiveness, is a common symptom of Parkinson's disease that often goes unnoticed in routine clinical assessments. To enhance symptom tracking, our system integrates a real-time facial recognition module that captures and analyzes facial expressions, along with voice and handwriting samples, to provide a more comprehensive evaluation of Parkinson's-related motor impairments. Patients are guided through a series of tasks, including facial exercises (such as smiling, raising eyebrows, and opening and closing their mouths), speaking predefined sentences into a microphone, and performing handwriting tasks on a digital writing pad. The system records facial muscle activation, voice modulation, and handwriting characteristics, such as stroke smoothness, letter size consistency, and writing speed. By analyzing these multimodal inputs, the system can identify subtle impairments that indicate disease progression. Additionally, it stores historical data, allowing healthcare professionals to compare current results with previous assessments to track changes over time. This integrated approach provides a more objective and data-driven method for monitoring Parkinson's disease, enabling more accurate diagnosis and personalized treatment planning.

A critical aspect of our AI-driven system is the use of explainable AI (XAI) techniques to improve the interpretability of its diagnostic decisions. Traditional deep learning models often function as "black boxes," making it difficult for healthcare professionals to understand how a diagnosis was reached. To overcome this limitation, our system employs feature attribution methods, such as SHAP values and saliency maps, which highlight the most influential data points in the decision-making process. This transparency not only enhances trust in AI-driven diagnoses but also allows clinicians to validate the model's predictions with their own expertise, ultimately improving the reliability and acceptance of AI in medical practice.

Furthermore, our system incorporates decision-level fusion (late fusion) techniques, which integrate insights from multiple AI models to produce a more robust diagnosis. Instead of relying on a single type of data, such as handwriting or facial expressions alone, the system

combines findings from multiple sources—including neuroimaging, speech analysis, and clinical records—to provide a holistic assessment of neurological disorders. This multimodal approach significantly improves diagnostic accuracy and reduces the likelihood of false positives or false negatives, ensuring more reliable outcomes for patients.

The implementation of cloud-based data storage and real-time monitoring further enhances the system's effectiveness. Patients can perform self-assessments at home, with their data securely transmitted to healthcare providers for remote analysis. This feature is particularly beneficial for individuals in rural or underserved areas with limited access to specialized neurological care. By enabling remote monitoring, the system allows for timely interventions and reduces the burden on healthcare facilities, making neurological healthcare more accessible and efficient.

While AI-based diagnostics present significant advantages, ethical considerations such as data privacy, security, and algorithmic bias must be carefully addressed. Our system follows stringent data protection regulations, including compliance with HIPAA and GDPR, to ensure patient confidentiality. Additionally, we continuously refine our models using diverse and representative datasets to mitigate biases and enhance generalizability across different demographic groups. By prioritizing ethical AI development, we aim to create a trustworthy and equitable solution for neurological disease detection and monitoring.

In conclusion, our AI-driven desktop application represents a transformative step in the early detection and monitoring of Parkinson’s disease, Alzheimer’s disease, and depression. By leveraging machine learning, deep learning, and multimodal data analysis, the system offers a more objective, accessible, and efficient alternative to traditional diagnostic methods. With real-time monitoring capabilities, explainable AI integration, and remote accessibility, this application has the potential to revolutionize neurological healthcare, providing patients and clinicians with a powerful tool for improved diagnosis and personalized treatment planning. As AI technology continues to evolve, its role in medical diagnostics will undoubtedly expand, paving the way for more proactive and effective management of neurological disorders.

1.1 BACKGROUND & LITERATURE SURVEY

Autism Spectrum Disorder (ASD) is a neurodevelopmental condition characterized by impairments in social communication and restricted, repetitive behaviors [1]. Traditional ASD diagnosis is based on behavioral assessments, which can be subjective and time-consuming. Machine learning (ML) techniques, particularly deep learning models such as Convolutional Neural Networks (CNNs), have been employed to analyze facial expressions and detect ASD features automatically [2]. Studies have demonstrated that CNN-based classifiers trained on facial landmark features can achieve over 93% accuracy in distinguishing ASD individuals from neurotypical controls [3].Recent research highlights the efficacy of multimodal approaches that integrate facial images, speech analysis, and eye-tracking data for ASD detection [4]. The use of Long Short-Term Memory (LSTM) networks to analyze speech patterns has shown promising results, particularly in detecting language impairments associated with ASD [5]. Further, Natural Language Processing (NLP)-based models have been developed to analyze textual and vocal responses from ASD individuals, enhancing classification performance [6].

Parkinson's Disease (PD) is a progressive neurodegenerative disorder that affects motor functions, causing tremors, rigidity, and bradykinesia [7]. Wearable technology combined with machine learning algorithms has significantly improved real-time PD detection [8]. Accelerometer and gyroscope sensors embedded in smart devices can effectively classify different stages of PD based on motor symptom patterns [9].Speech impairment is a key early symptom of PD, and Recurrent Neural Networks (RNNs) trained on voice recordings have demonstrated high accuracy in detecting PD-related dysarthria [10]. Moreover, deep learning-based gait analysis using 3D motion capture systems has improved PD symptom recognition, achieving an accuracy rate above 90% [11].

Alzheimer's Disease (AD) is the leading cause of dementia worldwide, posing significant challenges in early detection and treatment [10]. Neuroimaging techniques such as Magnetic Resonance Imaging (MRI) and Positron Emission Tomography (PET) scans have been widely used in AD diagnosis. Deep learning-based models, especially CNNs, have been extensively applied to analyze brain images, detecting structural abnormalities associated with AD [12]. A study utilizing a CNN-based classifier reported over 95% accuracy in identifying AD from MRI scans [13].Besides neuroimaging, speech and language processing techniques have also been explored for AD detection. Natural language processing (NLP) methods have been used to analyze linguistic patterns in patient speech, identifying cognitive impairments linked to AD progression [14]. Furthermore, multimodal fusion techniques combining imaging, speech, and clinical assessment data have shown improved predictive performance, facilitating early-stage diagnosis [15] [16].

Depression is a prevalent mental health disorder [17] with severe emotional and cognitive consequences [18]. Traditional diagnosis relies on self-reported assessments, but ML-driven models offer objective biomarkers for detection depression. Facial expression analysis using CNNs has been widely adopted, with deep learning-based emotion recognition systems achieving over 92% accuracy in identifying depressive states [19].Recent advancements have

integrated wearable sensors to monitor physiological signals such as heart rate variability (HRV), sleep disturbances, and electrodermal activity, enabling real-time depression detection [20]. Additionally, speech analysis using prosody-based features (pitch, tone, and rhythm) has improved automated depression classification [21].

Recent studies emphasize the importance of multimodal fusion techniques in enhancing the accuracy of neurological and neurodevelopmental disorder detection [22]. Combining visual (facial expressions), auditory (speech analysis), and physiological (sensor data) modalities has resulted in significant performance improvements across multiple disorders [23]. However, challenges remain in model interpretability, data privacy concerns, and cross-domain generalization. Addressing these issues will be critical for the future integration of AI-based diagnostic tools into clinical healthcare systems [24].

Alzheimer's disease (AD) is a progressive neurodegenerative disorder that significantly impairs memory, cognitive function, and behavior, making it the most common cause of dementia worldwide. Early diagnosis is crucial since significant neuronal damage occurs before clinical symptoms appear. Traditional diagnostic methods, including neuropsychological tests and clinical evaluations, often fail to detect AD at its earliest stages. This has driven the adoption of artificial intelligence (AI) and machine learning (ML) approaches, which can analyze complex medical data, identify early biomarkers, and improve diagnostic accuracy. Neuroimaging, particularly MRI, PET scans, and fMRI, plays a crucial role in AD detection by revealing structural and functional changes in the brain before cognitive decline becomes apparent.

AI-driven models have been applied to neuroimaging data using machine learning techniques such as support vector machines (SVM), logistic regression, and deep learning architectures like convolutional neural networks (CNNs). These models excel in detecting subtle structural variations in the brain, such as hippocampal atrophy, which are early indicators of AD. Multimodal learning, which integrates neuroimaging data with clinical and genetic information, has further improved diagnostic accuracy. However, challenges remain, including dataset heterogeneity, standardization issues, and the interpretability of complex deep learning models. Explainable AI (XAI) techniques, such as saliency maps and SHAP values, are being explored to make AI predictions more transparent and clinically interpretable.

In addition to Alzheimer's detection, AI has shown promise in diagnosing mental health disorders such as depression. Conventional diagnostic approaches rely on self-reported questionnaires and clinical evaluations, which are often subjective and limited in scalability. AI-powered natural language processing (NLP) and computer vision techniques can analyze textual and visual cues from patients, such as speech patterns, facial expressions, and writing styles, to detect signs of depression. Multimodal models that combine text and image data using fusion techniques have demonstrated improved accuracy in predicting depression severity. The integration of attention mechanisms and explainable AI further enhances these models by identifying key features contributing to the diagnosis, making them more reliable for clinical use.

Similarly, Parkinson's Disease (PD), the second most common neurodegenerative disorder, presents significant diagnostic challenges due to its gradual onset and overlapping symptoms with other conditions. Traditional PD diagnosis relies on subjective clinical assessments, which can lead to inconsistencies. AI-based models have leveraged clinical records, speech analysis, and handwriting assessments to enhance early detection. For instance, machine learning algorithms can identify vocal tremors, slowed speech, and micrographia early indicators of PD. Studies have shown that multimodal approaches, integrating speech, handwriting, and movement data, outperform unimodal models in detecting PD and predicting disease progression.

A key innovation in AI-driven PD diagnosis is **decision-level fusion (late fusion)**, where multiple independent models contribute to the final decision, improving robustness and interpretability. Unlike traditional binary classification, advanced AI models now stratify PD risk into multiple levels (low, moderate, high), allowing for more nuanced disease monitoring and early intervention. Additionally, the development of AI-powered web-based diagnostic platforms ensures accessibility for healthcare providers, enabling real-time patient assessments through clinical input forms, audio analysis, and digital handwriting evaluations. Such advancements hold immense potential for improving early diagnosis, treatment planning, and patient outcomes.

Despite these promising developments, significant challenges remain, including data availability, privacy concerns, and bias in AI models due to imbalanced datasets. Regulatory frameworks must evolve to support the integration of AI into clinical practice while ensuring ethical considerations are met. Future research should focus on standardizing data collection, improving model generalizability across diverse populations, and developing personalized AI-driven healthcare solutions. As AI technology continues to mature, its application in neurodegenerative disease diagnosis and mental health care will play a pivotal role in transforming medical diagnostics, ultimately leading to earlier interventions and better patient outcomes.

1.2 RESEARCH GAP

1.2.1 BRIDGING THE RESEARCH GAP IN ALZHEIMER'S DIAGNOSIS AND MANAGEMENT

A comprehensive review of the literature reveals significant gaps in the diagnosis and management of Alzheimer's disease. While existing studies have contributed valuable insights into specific aspects of the disease, they often lack an integrated, holistic approach that combines multiple diagnostic parameters for more effective patient monitoring and treatment planning. Our proposed solution aims to bridge these gaps by developing a unified system that enhances both early detection and long-term management of Alzheimer's disease.
Ebrahimi-Ghahnavieh et al. (2019) [25] conducted research focusing on Alzheimer's detection using MRI images, leveraging transfer learning techniques to enhance predictive accuracy. While MRI-based predictions play a crucial role in diagnosis, this study primarily centers on imaging analysis, neglecting other critical factors such as lifestyle habits, sleep quality, and patient history. Furthermore, the research does not incorporate MRI analysis into a broader, user-friendly system that enables continuous monitoring and treatment adjustments by healthcare professionals.

Similarly, Kuo et al. (2017) [26] introduced a wearable device designed to assess sleep quality, acknowledging the strong connection between neurodegenerative diseases and sleep disturbances. Although this research provides valuable insights into sleep patterns, it falls short of establishing a direct correlation between sleep quality and Alzheimer's prediction. The wearable device operates in isolation, without integration with MRI data, cognitive assessments, or other diagnostic tools that could enhance its predictive power.
Simon et al. (2016) [27] contributed a broader exploration of machine learning applications in Alzheimer's prediction, using background patient information as a key input. While this research highlights the potential of AI in early detection, it lacks a clear framework for visualizing predictions and translating them into actionable insights for long-term patient management. Additionally, it does not propose a unified platform that combines diverse data sources into a single, accessible system for healthcare providers.

1.2.1.1 PROPOSED SOLUTION

To address these limitations, our proposed system integrates multiple diagnostic parameters including MRI scan analysis, sleep quality monitoring via wearable devices, and comprehensive patient background information into a single, AI-driven platform. By combining these diverse data points, the system enhances the accuracy of Alzheimer's prediction and facilitates continuous tracking of disease progression. Moreover, it includes an interactive visualization tool that enables doctors to analyze medication reports, assess treatment effectiveness over time, and make necessary adjustments to optimize patient care.
This holistic approach not only improves diagnostic precision but also streamlines Alzheimer's management, transforming scattered research findings into a cohesive and

practical solution for both early detection and long-term treatment. By bridging these research gaps, our system empowers healthcare professionals with a comprehensive toolset to provide personalized care and enhance patient outcomes.

Table 1.Comparison of former research for Alzheimer's Disorder detection

Research	Research [25]	Research [26]	Research [27]	Proposed Solution
MRI scan related prediction.	✓	✗	✗	✓
Smart wearable for sleep quality measuring.	✗	✓	✗	✓
Alzheimer's prediction is based on user background information.	✗	✗	✓	✓
Alzheimer's medication report visualization.	✗	✗	✓	✓

1.2.2 BRIDGING RESEARCH GAPS IN PARKINSON'S DISEASE DIAGNOSIS THROUGH AI-DRIVEN MULTIMODAL APPROACHES

The early diagnosis of Parkinson's Disease (PD) using robust machine learning (ML) techniques has been achieved in the recent past. Nevertheless, the research still has significant deficits that must be addressed, even though the advancements in this line of study are quite promising. This paper has discussed various research gaps associated with the existing literature and is outlined below as a way of showing the areas that the proposed research would seek to fill the gaps as follows:

Table 2.Comparison of former research for Parkinson's Diagnosis detection

Feature / Approach	[28]	[29]	[30]	Proposed Solution
Clinical data-based prediction	✓	✗	✗	✓
Speech/audio-based analysis	✗	✓	✗	✓
Handwriting/ motor symptom analysis	✗	✗	✓	✓
Use of separate models for each data type	✗	✗	✗	✓
Late fusion-based multimodal integration	✗	✗	✗	✓
Real-time prediction via web application	✗	✗	✗	✓
Multi-level disease progression indicator (Green-Yellow-Red)	✗	✗	✗	✓
Feature selection using statistical methods	✓	✗	✗	✓
Temperature-scaled softmax in fusion stage	✗	✗	✗	✓

There is, nonetheless, one intriguing omission: voice analysis combined with emotion detection for accurate, timely identification of PD. Although there is a body of work including Research [31] that aimed at investigating the possibility of diagnosing PD using only voice data, there is a lack of understanding of how to improve models using the data containing emotional information. Using this method in combination with changes in the voice, it is possible to have additional important markers associated with the early emotional changes related to PD. But as pointed out by Research [29] and Research [30], there is a strong missing link between this multiple focus approach. This gap is important because, at times, it can be hard to detect emotional dysregulation and when it is detected, it is likely to appear alongside motor symptoms which make it possible to increase the chances of getting high accuracy when using voice-based ML models.

One of the domains where prior literature is rather scarce is the use of handwriting images for PD's identification. Research [29] has focused on this area wherein through computer analysis of writings for features like strokes and pression, the first signs of PD are detected. Nevertheless, this approach is not followed by everyone and as has been illustrated in Research [31] and Research [30], this useful diagnostic tool is often ignored. Analysis of handwriting samples of patients with PD has been found to be quite helpful to identify the extent of motor deterioration. The lack of consistency in using this approach for the analysis of handwriting to enhance the great mystery of the predictive solutions that are on offer is quite apparent. To this end the proposed research aims at filling this research gap through the standardization of handwritten image biomarkers together with other biomarkers.

The largest limitation to evidence in the literature, nonetheless, is the fact that there are relatively few studies that use a multimodal approach to diagnose Parkinson's disease. Incorporation of information from more than one modality, for instance voice, handwriting and gait analysis, is likely to be a more accurate diagnosis than using a single modality. Still, as seen in Research [31], Research [29], and Research [30], most of today's investigations are based on single-modal datasets. This segmentation approach hampers the solidity of the techniques of prediction of PD since it does not take into consideration the complexity of the PD. The following study plan has been designed with the purpose of filling in the gap and building a robust multimodal ML model that integrates various physiological and behavioral features so that early PD diagnosis becomes more accurate.

Last but not the least; a rather critical shortfall in the existing research is the integration of real time application and data processing with these predictive models. To the authors' knowledge, no prior studies adequately capture the process by which these findings were implemented in practice, especially regarding how to create diagnostic tools that can be used in real time by clinicians in their daily practice. Thus, the proposed research aims to leave no gap in the knowledge of CVD risks for chronic high-risk patients, as it is going to present a model for decision-making not only as a written text but as an operational Web/Mobile application that will be easy to use. It will also allow for real-time data analysis and decision-making for clinicians and patients for early diagnosis and further follow-up of the disease.

In view of this, there is promising work that has been done in the early detection of PD using machine learning techniques, but the following areas still present major research challenges. They are as follows; the incorporation of affective insight into the voice signal processing, the normalization of graphical handwriting images, the employment of MDA approach, and finally the creation of time-sensitive, clinically feasible tools. The lack of knowledge of these gaps is

critical to the development of the field and the early diagnosis of Parkinson's disease and its management.

1.2.3 BRIDGING RESEARCH GAPS IN AUTISM DETECTION: ADVANCING AI-DRIVEN MULTIMODAL APPROACHES FOR EARLY DIAGNOSIS

Despite significant advancements in facial image recognition for autism detection, many researchers have primarily focused on single-model approaches that often overlook crucial variables necessary for accurate ASD identification. These models, while useful, are limited by inconsistencies in image quality, lighting, and facial expressions, as well as a lack of diversity in datasets. To address these limitations, there is need for growing multimodal approaches that combine both facial images and text-based data. By integrating textual information with facial analysis, researchers can capture a broader range of ASD indicators, leading to more robust and comprehensive models. This approach has the potential to fill existing research gaps, enhance prediction accuracy, and improve the generalizability of autism detection methods across different populations.

Instead of concentrating on specialized consultants, current research efforts are increasingly directed towards the development of tools and systems that general practitioners (GPs) may employ. This change is beneficial for everyone since it enables general practitioners (GPs), who are frequently the initial point of contact in the healthcare system, to detect autism early on, especially in areas with limited access to specialized treatment. Developing accurate, comprehensible, and user-friendly technologies for non-specialists is the primary area of unmet research need. To ensure early identification even in the absence of specialized expertise, these systems must close the knowledge gap that exists between general practitioners and higher-level consultants.

The early detection and diagnosis of mental health issues, which is essential for prompt care, is the primary area of this project's deficit. Treatment for these illnesses is frequently postponed since current techniques are frequently unable to identify them early. The main goal of the project is to create an AI-driven system that mainly uses cutting-edge machine learning methods for early detection and management to address this. The specific gaps are related to my component highlighted by the following key points :

Study "A" [32] Recent developments in deep learning (DL) have demonstrated potential for using facial image analysis to automatically diagnose autism spectrum disorder (ASD). Still in its early phases, current research is constrained by tiny, homogeneous datasets, which may result in misdiagnosis. Building complete datasets with more than just facial photographs is crucial to enhancing accuracy and reliability. Furthermore, concentrating only on facial analysis ignores other important aspects of ASD identification. Future studies could build on these models by adding more factors and investigating easily available, reasonably priced options, such as smartphone apps, for more comprehensive diagnosis and rehabilitation. These developments would improve the accessibility and efficacy of DL-based ASD screening systems.

Study "B" [33] In our research, we identified key characteristics associated with autism spectrum disorder (ASD), finding that the A9 score, which indicates a version to physical

contact, is a significant factor in adults and combined datasets. For children, the A4 score, which reflects difficulty in understanding others' emotions, emerged as the primary trait. However, the analysis was constrained by the relatively small size of the available datasets.

Additionally, our research primarily relied on raw data, without incorporating image processing techniques. This highlights a critical gap, as integrating image processing with raw data could potentially lead to more accurate and comprehensive models. To address these issues, we plan to apply advanced classification and clustering models to larger datasets and explore deep neural network-based approaches that can simultaneously learn features, classification, and clustering metrics.

Study "C' [34]" Currently, there is a big gap in the creation of diagnostic tools that are accurate, scalable, and easily accessible: multimodal data, integration is not given enough attention, including text-based questionnaires and facial images, in data-driven mobile applications for early-stage autism detection. Although the goal of these applications is to identify ASD by data driven methods, they frequently fail to consider the value of adding image-based data, which can improve the diagnosis' precision and dependability. Furthermore, the lack of standardized information makes it more difficult to develop dynamic, responsive systems that can track patients' progress over time. Future studies should concentrate on filling in these gaps by creating all-encompassing digital diagnostic systems that can adjust to the specific requirements of each patient, guaranteeing more efficient and customized care.

Table 3.Comparison of former research for Autism Disorder detection

Application Reference	Face Images Detection	Text Base Data Gathering	Get the Feedback through the report base classifications	Mobile Application	Use Multimodal Approach
[A]	Yes	No	No	No	No
[B]	No	Yes	No	No	No
[C]	No	No	No	Yes	No
[D]	No	Yes	No	Yes	No
[E]	Yes	Yes	No	No	Yes
Proposed system	Yes	Yes	Yes	Yes	Yes

1.2.4 BRIDGING THE RESEARCH GAP: MENTCARE AI – A MULTI-MODAL NEURAL NETWORK APPROACH FOR EXPLAINABLE DEPRESSION DIAGNOSIS

Millions of individuals worldwide suffer from depression, a common mental health illness that makes early diagnosis and treatment extremely difficult. There is still a study gap in the thorough application of multi-modal techniques to diagnose depression by merging various data inputs, such as text, facial expressions, and speech, despite advances in machine learning and artificial intelligence for mental health applications. Many previous research work have concentrated on single-modal methods that employ facial, audio, or textual data to diagnose depression. Although these techniques show promise, they frequently fall short of the depth and accuracy that come from multi-modal analysis. Moreover, rather than offering a comprehensive examination of depression severity levels, most recent research has focused on categorization tasks for determining if an individual is depressed. This restricts these models' practical application in actual clinical settings. The suggested remedy, "Mentcare AI," seeks to bridge this research gap by employing multi-modal neural network techniques to incorporate text and visual data for more accurate depression diagnosis. When XAI is combined with these

models, it offers a clearer grasp of the reasoning behind diagnosis, giving medical professionals more insight into the prediction process. This improves the system's accuracy while also boosting healthcare specialists' confidence in it. By comparing the proposed solution with existing models, "Mentcare AI" shows promise in advancing the field of AI-driven mental health applications, offering a more holistic and explainable approach to depression diagnosis.

Table 4.Comparison of former research for Depression Disorder detection

Device/ Application	Depression Detection	Multi-modal Approach	Model Explainability	Attention Mechanism	Depression Level Detection	Real-time Data Integration
Research [35]	Yes	No	No	No	No	No
Research [36]	Yes	No	No	No	No	No
Research [37]	Yes	No	No	Limited	No	No
Research [38]	Yes	Limited	No	Yes	No	No
Research [39]	Yes	No	No	No	No	Yes
Research [40]	Yes	Yes	No	Yes	No	Yes
Proposed system	Yes	Yes	Yes	Yes	Yes	Yes

1.3 RESEARCH PROBLEM

1.3.1 ALZHEIMER'S DISEASE DIAGNOSIS AND MANAGEMENT

Problem 1: The Challenge of Early Diagnosis and Pressure on Healthcare Systems Alzheimer's disease (AD) presents a growing global challenge, particularly with the increasing aging population. The demand for efficient and accurate diagnosis and management is critical to alleviating the immense pressure placed on healthcare providers. Early detection is vital, as timely intervention can slow disease progression and improve the quality of life for patients. However, despite advancements, current diagnostic methods are inadequate, primarily relying on manual analysis of MRI scans, cognitive evaluations, and patient history, which can be both time-consuming and subject to human error. The absence of a comprehensive, data-driven diagnostic system further exacerbates delays and hinders the optimal management of AD.

Problem 2: The Bottleneck in Manual MRI Scan Interpretation The manual interpretation of MRI scans remains a significant bottleneck in diagnosing Alzheimer's, particularly in resource-limited settings. Although neuroimaging has made strides, subtle changes in brain structures linked to Alzheimer's still require expert radiologists. Moreover, traditional diagnostic methods do not incorporate other crucial patient data such as lifestyle, sleep patterns, or demographic information, which could offer important insights into the risk and progression of AD.

Problem 3: Lack of Unified Systems for Data Integration An essential gap in AD diagnosis is the lack of systems that unify diverse patient data from MRI images to wearable data tracking sleep quality and demographic details into a single platform for comprehensive analysis. The absence of such integrated systems hinders healthcare providers' ability to make informed decisions and results in suboptimal long-term disease management.

1.3.2 PARKINSON'S DISEASE EARLY DETECTION

Parkinson's Disease (PD) is a complex and progressive neurodegenerative condition that affects both motor as well as non-motor functioning and is associated with a significant reduction in the quality of life of patients. Early and accurate diagnosis of PD is crucial, as early intervention will slow down the progression of symptoms, improve patient outcome, and reduce the long-term economic burden on healthcare systems. However, conventional diagnosis is still highly reliant on subjective clinical evaluations, which are prone to human variability, differences in expert opinion, and delayed identification. A critical requirement is the availability of automated, objective, and multimodal techniques that can facilitate early diagnosis and continuous monitoring of Parkinson's Disease.

Over the past decade, a number of research works have been aimed at leveraging machine learning (ML) techniques for facilitating PD detection automation. These approaches typically utilize features of a single modality—either clinical symptoms, speech pathology, or handwriting impairment. For instance, studies such as Prashanth & Roy [28] utilized clinical data with question response to develop predictive models, while Lahmiri et al. [41] utilized dysphonia characteristics from voice recordings to distinguish PD from healthy controls. Similarly, Kotsavasiloglou et al. [42] explored handwriting patterns to detect motor dysfunctions in PD patients. Although these unimodal approaches have provided promising results, they lack generalizability, suffer from false positives or false negatives, and fall short in capturing the extremely intricate character of PD symptoms.

One inherent shortcoming of existing research is the absence of fusion-based multimodal approaches that can meaningfully fuse information from diverse sources of data—clinical assessment, speech characteristics, and handwriting features. While each of these modalities has individual diagnostic value, their combination offers more insight into disease progression and symptom heterogeneity. Experiments by Wang et al. [43] and Dissanayaka [44] implicated that hybrid combinations with more than one domain of features significantly improve prediction performance and stability. However, there is a gap in the research on developing practical, balanced, and interpretable fusion mechanisms which can efficiently combine such heterogeneous inputs in real-world clinical settings.

Moreover, it is not just the detection of the presence or absence of Parkinson's Disease that is a challenge, but also determining the level of severity or the progression of the disease. Most recent research confines the diagnosis to a dichotomous classification PD or non-PD and sidesteps the spectrum of symptom development the patients experience. This dichotomous framework is insufficient to support treatment decisions, rehabilitation strategies, and counseling for patients. The imperative for a risk stratification system in addition to classification that provides doctors with a progression-based diagnosis, e.g., early-stage, mid-stage, or advanced PD, is urgent.

In the current research, a novel solution is introduced to address the above-mentioned shortcomings by formulating a multi-model fusion system that combines the prediction of three autonomous machine learning models learned on unique modalities: clinical data, speech, and handwriting. The integrated system is also augmented with a Multi-Level Disease Progression Indicator, which categorizes patients into three disparate risk categories Low Risk (Green), Moderate Risk (Yellow), and High Risk (Red). This approach is in accordance with the true need for precise, interpretable, and patient-specific diagnoses, ultimately to reduce diagnostic delays and provide healthcare professionals with meaningful decision-supporting tools.

Along with this, an intuitive and operational web-based interface is implemented to serve as the system's front-end. The interface offers users patient data input via forms, microphone input for voice input, and handwriting acquisition through smart tablet integration. The backend is accompanied by the late fusion logic in a bid to create online predictions. Besides

ensuring clinical environments' usage and scalability of the solution presented here, this brings together the gap between AI research, healthcare application.
Lastly, the research problem addressed in this paper is the lack of strong, interpretable, and multi-domain diagnostic systems for Parkinson's Disease. The solution proposed introduces a holistic approach that integrates three fundamental modalities with a risk stratification process, hence generating a more precise and actionable diagnostic outcome for early diagnosis and disease tracking.

1.3.3 DEPRESSION DIAGNOSIS WITH AI

Problem 1: Subjectivity in Traditional Diagnostic Approaches Depression is a widespread mental health condition that is often underdiagnosed or misdiagnosed, leading to delayed or inadequate treatment. Traditional diagnostic approaches, which rely on self-reported questionnaires and clinical interviews, are subjective and can vary based on the therapist's experience. This lack of consistency and the challenges in obtaining comprehensive data from patients who are unable to express their symptoms make accurate diagnosis difficult.

Problem 2: Single-Modal Diagnostic Models Current AI-based diagnostic models for depression largely focus on single-modal data, such as text-based analysis or facial emotion detection. These models do not fully capture the complexity of depression, which requires a multi-dimensional approach for accurate diagnosis. Additionally, the "black box" nature of many AI systems raises concerns about their transparency and interpretability, making it difficult for clinicians to trust the results.

Problem 3: The Need for Multi-Modal Approaches This research aims to improve depression diagnosis by integrating text and facial emotion data using advanced multi-modal methods. Two primary approaches will be explored: a Weighted Average method and a Multi-modal Neural Network. These approaches will be tested using real-time data collection via a mobile app, which will allow for more personalized, timely, and accurate diagnosis. Furthermore, incorporating explainable AI (XAI) will ensure that clinicians can understand the reasoning behind AI-driven predictions, improving trust and confidence in the system.

1.3.4 AUTISM SPECTRUM DISORDER (ASD) DIAGNOSIS

Problem 1: Limitations of Traditional Diagnostic Methods Traditional diagnostic techniques for Autism Spectrum Disorder (ASD), such as the Autism Diagnostic Interview-Revised (ADI-R), are manual, time-consuming, and expensive. These methods often require several hours to complete, leading to delays in diagnosis and early intervention. This inefficiency underscores the need for a faster, more reliable diagnostic solution.

Problem 2: Shortage of Clinical Data for Early Diagnosis A significant challenge in ASD diagnosis is the lack of available clinical data, particularly in children under the age of four and a half. This shortage of data coupled with the difficulty of collecting data from young children

with limited communication abilities hinders the development of accurate machine learning (ML) and deep learning (DL) models for early diagnosis.

Problem 3: Limited Datasets for Machine Learning Models The small size of available ASD datasets limits the power and accuracy of clustering and classification models. This constraint affects the robustness and reliability of existing diagnostic tools. This research seeks to overcome these limitations by incorporating larger datasets and employing more sophisticated classification and clustering techniques, using deep neural networks to simultaneously learn features and perform accurate classification and clustering.

Problem 4: Multi-Modal Data Integration for Accurate Detection One of the critical challenges in early ASD diagnosis is integrating multimodal data, such as facial images and text-based questionnaires, into a coherent machine learning model. The variability in data structures and processing requirements complicates the integration of these different data sources. This research aims to develop innovative methods to combine these data types into a unified, reliable model that improves diagnostic accuracy for ASD.

1.4. OBJECTIVES

1.4.1 MAIN OBJECTIVE

The primary objective of this research is to develop an AI-driven, multimodal detection and monitoring system for Autism Spectrum Disorder (ASD), Parkinson's disease, Alzheimer's disease, and depression. This integrated system will combine facial analysis, speech recognition, text-based assessments, and wearable sensor data to enhance early detection, improve diagnostic accuracy, and facilitate efficient management by healthcare professionals. By leveraging advanced machine learning (ML), deep learning (DL), and Explainable AI (XAI), the system will provide a comprehensive, objective approach to diagnosing and monitoring these conditions. Traditional clinical diagnoses often rely on subjective assessments, which can lead to misdiagnosis or delayed intervention. This research aims to overcome these challenges by integrating multiple data sources such as facial recognition (using VGG19), speech analysis, questionnaire-based assessments (via Random Forest), and wearable sensors capturing subtle symptoms and offering a more accurate and holistic evaluation. This system will not only assist healthcare professionals in making evidence-based decisions but also provide real-time insights to track symptoms and recommend personalized treatments.

The proposed AI-driven system aims to bridge the gap between traditional medical diagnoses and modern AI-assisted technologies. It will be designed as a user-friendly desktop and mobile application, enabling individuals to conduct preliminary screenings at home. Early detection is crucial in conditions like Alzheimer’s and Parkinson’s, where timely intervention can slow disease progression, and in ASD and depression, where early identification allows for more effective therapeutic interventions. By reducing reliance on subjective evaluations and automating symptom tracking, the system will act as a Clinical Decision Support System (CDSS), improving the precision and efficiency of diagnostics. Ultimately, the goal is to make neurological and mental health diagnostics more accessible, improve personalized treatment plans, and provide continuous monitoring to ensure optimal patient care and outcomes.

1.4.2 SPECIFIC OBJECTIVES

To achieve the main research objective, the study is divided into the following sub-objectives:

1.4.2.1 DEVELOPING MACHINE LEARNING-BASED DIAGNOSTIC MODELS

- Design and implement machine learning models to analyze medical data (e.g., MRI scans for Alzheimer's, voice recordings for Parkinson's, facial images for ASD, and facial expressions for depression) to automate diagnosis and improve accuracy across different diseases.
- Incorporate data from wearable devices (e.g., sleep quality metrics, gait patterns, etc.) for continuous monitoring and enhanced disease understanding.

1.4.2.2 MULTIMODAL DATA FUSION FOR ENHANCED DIAGNOSTIC ACCURACY

- Integrate data from multiple sources such as MRI scans, behavioral questionnaires, speech recordings, facial expressions, and wearable sensor data to provide a holistic view of the patient's health.
- Develop a fusion model combining deep learning (e.g., VGG-19 for facial recognition, SBiLSTM for behavioral data, and multimodal neural networks) for improved disease detection and progression tracking.

1.4.2.3 PERSONALIZED TREATMENT PLANNING AND MONITORING

- Use the integrated system to design personalized treatment plans by analyzing the patient's medical background, behavior, and physiological data (e.g., sleep patterns, tremors, handwriting).
- Develop a real-time monitoring system that tracks disease progression and recommends treatment modifications based on continuous data collection from wearables and diagnostic tools.

1.4.2.4 DEVELOP USER-FRIENDLY WEB AND MOBILE APPLICATIONS

- Create web and mobile platforms that allow healthcare professionals to access real-time data, diagnostic results, and patient progress, facilitating better decision-making and patient management.
- Develop mobile applications to gather real-time data from patients (e.g., mood assessments, facial expressions, etc.) and integrate these insights into the overall diagnostic model.

1.4.2.5 INTEGRATE EXPLAINABLE AI (XAI) FOR MODEL TRANSPARENCY

- Implement XAI techniques to ensure that the diagnostic system's decision-making process is transparent and interpretable, helping clinicians understand how predictions are made and increasing trust in AI-driven decisions.
- Provide clear explanations for the features influencing depression severity or the diagnosis of other conditions, enhancing clinical adoption.

1.4.2.6 VALIDATION AND CLINICAL INTEGRATION

- Conduct clinical trials to validate the developed system's accuracy, usability, and impact in real-world healthcare settings.
- Assess the system's effectiveness in diagnosing and managing neurological and psychological disorders across diverse populations and clinical environments.

1.4.2.7 EVALUATE SYSTEM PERFORMANCE AND GENERALIZABILITY

- Analyze the performance of the integrated models across diverse demographic groups to ensure that the diagnostic system generalizes well across different patient profiles.
- Evaluate the performance of multimodal models in various clinical settings and determine the optimal approach for each condition (e.g., depression, Alzheimer's, Parkinson's, ASD).

1.4.2.8 DEVELOP PROGRESS REPORTS AND TREATMENT RECOMMENDATIONS FOR HEALTHCARE PROVIDERS

- Create an automated system for generating comprehensive progress reports that include patient status, trends, and suggested adjustments to the treatment plan based on real-time data analysis.
- Enable healthcare professionals to make more informed decisions about patient care by providing continuous monitoring and real-time feedback.

1.4.2.9 OPTIMIZE THE SYSTEM FOR CLINICAL USE

- Evaluate and recommend the most effective model for each condition (depression, Alzheimer's, Parkinson's, ASD) based on clinical evaluations and performance metrics.
- Focus on optimizing system usability, accuracy, and interpretability to ensure seamless integration into clinical workflows.

2.0 METHODOLOGIES

2.1 SYSTEM OVERVIEW

In an era where technology bridges gaps in healthcare, AI-driven mental health monitoring is transforming early disease detection and patient care. As illustrated in Figure 4 – Overall System Diagram, this innovative system integrates wearable sensors, machine learning, and real-time data analysis to detect and monitor Depression, Autism, Alzheimer's, and Parkinson's. The process begins with comprehensive data collection, capturing key physiological and behavioral markers unique to each condition from cognitive decline in Alzheimer's to speech irregularities in Autism and motor impairments in Parkinson's. Advanced AI algorithms then analyze these patterns, identifying subtle deviations that indicate early symptoms. Patients undergo continuous monitoring and analysis, ensuring that their health trends are assessed dynamically over time. By leveraging predictive analytics, the system not only detects diseases but also provides insights into severity levels, generating personalized reports for doctors to support tailored treatment plans. This multi-faceted, patient-centric approach represents the future of mental health diagnostics, making early intervention smarter, faster, and more effective than ever before.

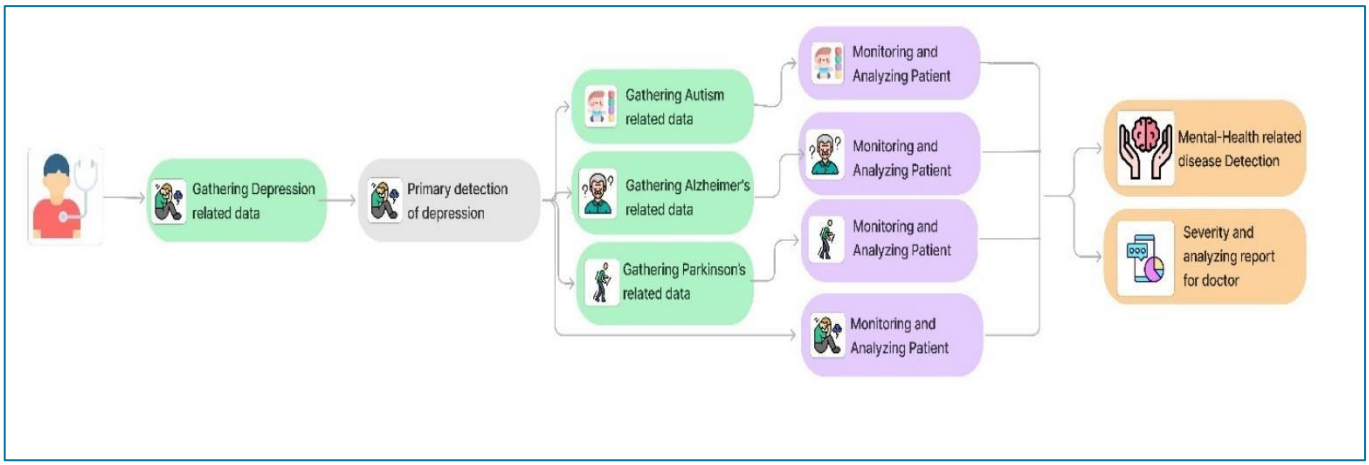

Fig 1. Overall System Diagram

2.2 HYBRID CNN-SVM AND MACHINE LEARNING APPROACH FOR MULTI-MODAL ALZHEIMER'S DISEASE CLASSIFICATION

2.2.1 COMPONENT DIAGRAM

This section explores the theoretical foundations and problem formulation required for accurate, efficient, and early prediction of Alzheimer's disease (AD). As illustrated in Figure 5, the proposed system adopts a multimodal approach to enhance diagnostic precision, advancing beyond traditional single-source classifiers toward a comprehensive, end-to-end predictive framework. Our research is structured around three core components:

i. Multimodal feature extraction, in which structural features are extracted from MRI scans using CNN-based methods and clinical features are parsed from structured CSV datasets (e.g., MMSE scores, APOE genotype, age) sourced from repositories like ADNI and OASIS.
ii. Multimodal feature fusion, where outputs from the neuroimaging and clinical data models are integrated for synergistic interpretation.
iii. Multimodal AD detection, where the fused features support final Alzheimer's classification.

By following this integrated framework, the system achieves a more reliable and holistic assessment of an individual's risk, supporting early clinical intervention.

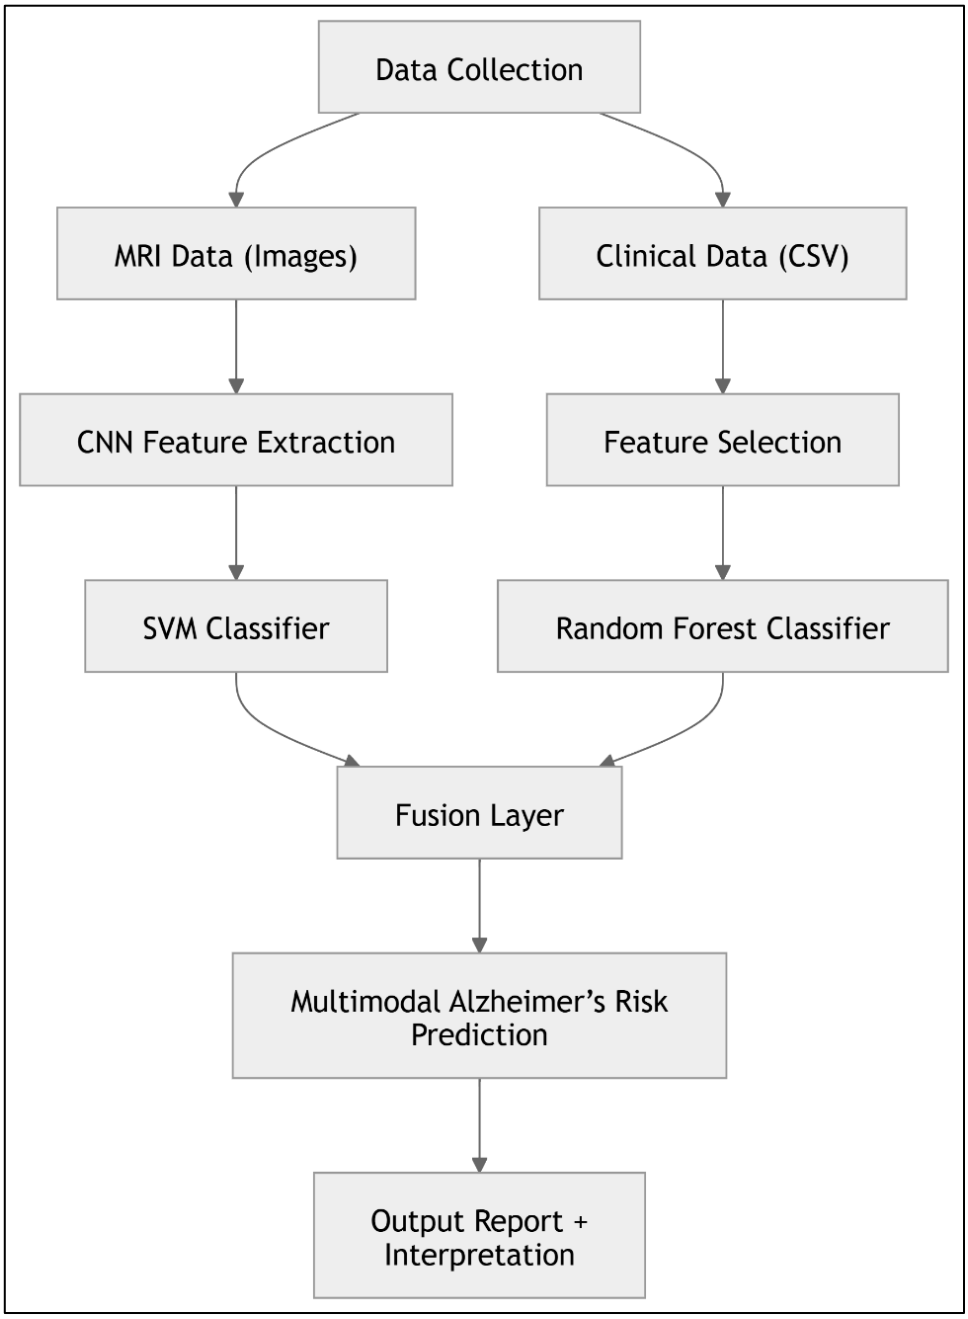

Fig 2.4 Descriptive Flowchart

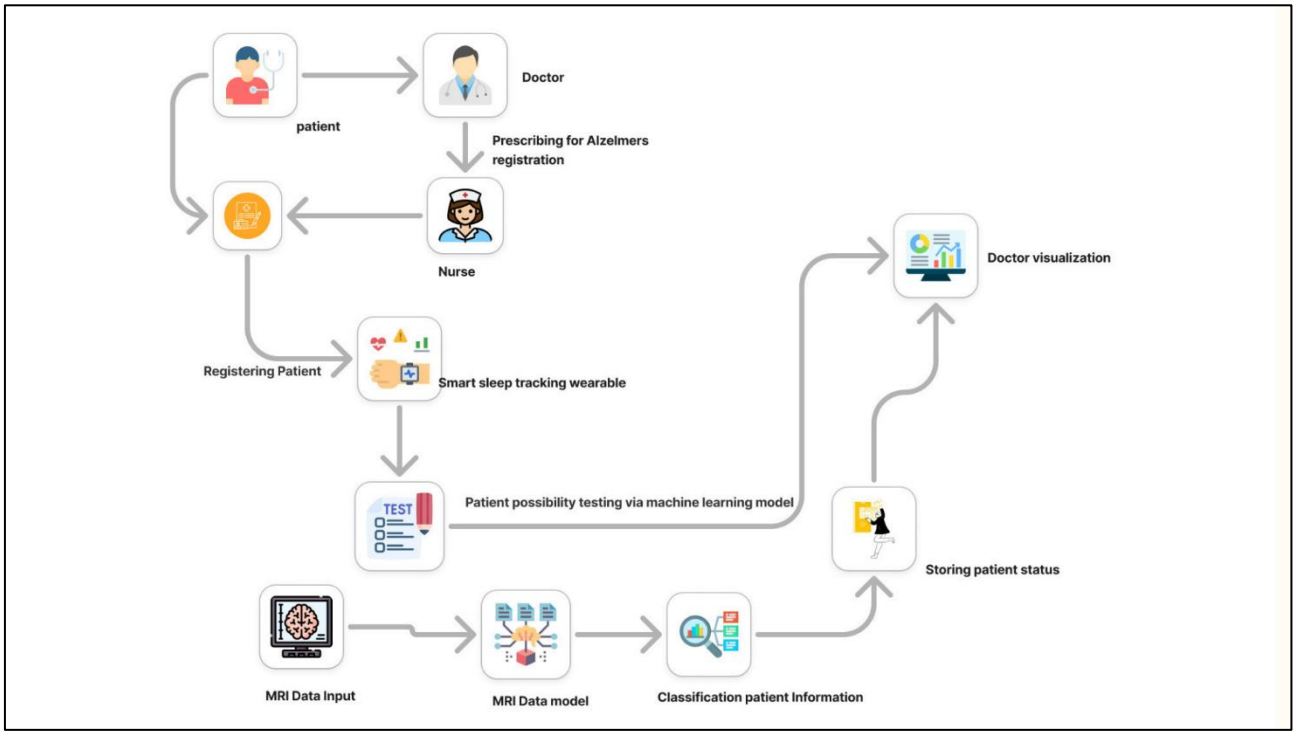
The methodology introduces a multimodal data fusion framework tailored for early Alzheimer's disease prediction by combining high-resolution MRI images and structured clinical data. The process begins with the acquisition of publicly available datasets, which include both neuroimaging scans and detailed clinical information. Two specialized predictive models are employed: a CNN+SVM-based architecture processes the MRI data, while a Random Forest model analyzes the clinical CSV records. The outputs from these models are subsequently fused to generate a unified Alzheimer's risk prediction, enhancing diagnostic accuracy through data complementarity.

2.2.2 PROPOSED METHODOLOGY

Fig 3.Architecture diagram of the methodology



The proposed methodology for the early detection of Alzheimer's Disease (AD) integrates patient-centric data acquisition, multimodal input processing, and machine learning-based prediction to establish an efficient and practical diagnostic framework. As visualized in the methodology diagram (Figure X), the system is designed to support early-stage identification of AD by combining structural brain imaging (MRI) and auxiliary physiological data, such as sleep patterns, collected through wearable devices. The process begins with the patient visiting a doctor, who then prescribes screening for potential Alzheimer's symptoms. Upon receiving the prescription, a nurse facilitates the registration of the patient into the system, ensuring the patient's information is securely captured and linked with smart wearable devices.

Smart wearable integration in the system introduces an innovative element continuous physiological monitoring. Research shows that sleep disturbances and circadian rhythm abnormalities are early indicators of cognitive decline and neurodegenerative conditions, including Alzheimer's disease [45]. By capturing real-time behavioural signals via wearable sensors, the system strengthens the predictive foundation by complementing MRI-based structural insights. After patient data acquisition is completed, the methodology initiates its core machine learning component, which tests the patient's likelihood of having Alzheimer's using pre-trained predictive models.

The system operates with two primary models: a deep learning model using convolutional neural networks (CNN) integrated with a support vector machine (SVM) classifier to process and interpret MRI scans, and a separate Random Forest classifier that analyses clinical

features derived from structured data (e.g., demographic information, cognitive test scores, genetic markers). CNNs are particularly effective in capturing spatial features from MRI data, and their combination with SVM enhances classification performance in imbalanced datasets a common issue in medical applications [46]. Meanwhile, Random Forests are chosen for their robustness and high performance in handling structured health datasets, particularly in the presence of non-linearity and missing values [47].

These two modalities operate in parallel, enabling the system to process heterogeneous data types concurrently. The multimodal outputs are then fused to generate a comprehensive patient classification. This step ensures that the final diagnostic decision is based on both anatomical markers from MRI data and physiological/cognitive indicators. The patient's predicted status is subsequently stored in a centralized repository, ensuring their health profile and progression are accessible over time. This historical storage mechanism is crucial for long-term disease monitoring and personalized intervention planning.

The final step involves visualizing the prediction outcomes and clinical history through a doctor-friendly dashboard. This interface transforms raw predictions into interpretable reports and graphs that can be easily understood by healthcare professionals, enhancing their decision-making process. Such explainable output is essential for fostering trust in AI-assisted diagnostics and ensuring ethical implementation in clinical practice [48]. Overall, the methodology aims to deliver a scalable, accessible, and data-driven solution for early Alzheimer's disease screening, leveraging the strengths of both medical imaging and structured clinical data. Diagnosis. The subsequent sections delve into the detailed implementation and evaluation of this model.

2.2.2.1 DATA COLLECTION LAYER

The data collection layer is a crucial foundation for the development of the Alzheimer's disease detection system, enabling both image-based and structured data-based predictions. Two publicly available datasets from Kaggle were utilized to support the multimodal nature of this research. The first dataset, obtained from Kaggle - Alzheimer's Disease Dataset, consists of structured clinical and demographic data provided in CSV format. It includes essential variables such as gender, age, education level, socioeconomic status, MMSE scores, and clinical diagnostic labels (e.g., demented, non-demented). This dataset is highly suitable for classical machine learning algorithms like Random Forest, which can use these features to predict the likelihood of Alzheimer's in individuals. The structured nature of the data allows for efficient preprocessing steps, including normalization, encoding of categorical variables, and missing value treatment, thus facilitating high-quality input for supervised classification tasks.

The second dataset, sourced from Kaggle - OASIS MRI Images, contains T1-weighted MRI brain scans from the OASIS (Open Access Series of Imaging Studies) repository. These images are labelled with clinical conditions and are critical for developing and training the CNN-SVM hybrid model for visual feature extraction and classification. This neuroimaging dataset enables the system to identify structural brain changes typically associated with

Alzheimer's disease, such as hippocampal atrophy. Together, these datasets provide complementary perspectives clinical and anatomical enabling a multimodal prediction framework. The integration of structured patient records with visual brain imaging enhances the robustness, precision, and clinical relevance of the detection system, contributing to early and more accurate diagnosis.

2.2.2.1.1 MRI ANALYZING DATASET

In this research, one of the core components of the Alzheimer's disease detection framework involves the use of a curated MRI image dataset titled "OASIS Alzheimer's Detection", hosted on Kaggle by user Ninad Aithal. This dataset is derived from the Open Access Series of Imaging Studies (OASIS), a reputable neuroimaging project that provides publicly accessible MRI scans and metadata to support research in the domain of cognitive aging and Alzheimer's disease. The specific version of the dataset used contains over 86,400 pre-processed image slices, sorted into four distinct categories based on the severity of dementia: Non-Demented, Very Mild Dementia, Mild Dementia, and Moderate Dementia. This class-based organization supports supervised learning approaches and makes the dataset highly suitable for training deep learning models aimed at Alzheimer's stage classification [49].

The MRI data provided are T1-weighted structural scans, which are commonly used in neuroimaging research due to their ability to offer high contrast between brain tissues—particularly grey matter, white matter, and cerebrospinal fluid. These contrasts are vital for identifying structural changes such as hippocampal atrophy or cortical thinning, which are hallmark features of Alzheimer's pathology [50]. The dataset includes a wide distribution of labelled data: approximately 67,200 images belong to the non-demented category, 13,700 to Very Mild Dementia, 5,000 to Mild Dementia, and 488 to Moderate Dementia. While the class distribution is imbalanced, it reflects real-world demographics, where early stages of the disease are more common than advanced dementia during diagnosis.

Each of the four directories in the dataset contains many axial 2D image slices extracted from volumetric MRI scans. The data are structured in such a way that they can be directly fed into convolutional neural networks (CNNs) for feature extraction and classification tasks. The presence of a substantial number of image slices for each subject ensures adequate variability and representation of anatomical features, which enhances the training potential of deep learning models. Prior to modelling, the image data typically undergo preprocessing steps including resizing (e.g., 224x224 pixels for VGG-based models), grayscale normalization, histogram equalization, and augmentation strategies like flipping or rotation to improve model generalization [51].

One of the advantages of this dataset is that it allows for binary, multiclass, and hierarchical classification experiments. For example, binary classification can be performed by grouping all stages of dementia into one class and comparing them against the non-demented class. Alternatively, fine-grained multiclass models can be built to distinguish between all four categories individually, enabling stage-wise detection of Alzheimer's progression. In this study, a CNN model (VGG19 architecture) is used to extract spatial features from MRI slices,

followed by a Support Vector Machine (SVM) classifier that processes the high-dimensional embeddings for final classification. This hybrid approach has proven to enhance accuracy in many neuroimaging applications by leveraging the representational power of CNNs and the decision-boundary sharpness of SVMs [52].

Another strength of this dataset lies in its compatibility with transfer learning. Given the image similarity to natural image structures, pretrained models such as VGG, ResNet, and EfficientNet can be fine-tuned using the OASIS image slices. This reduces training time and improves model performance, especially in the context of limited labelled medical imaging data [53]. However, to ensure clinical relevance, careful validation and evaluation are conducted using appropriate metrics like accuracy, precision, recall, F1-score, and ROC-AUC, as well as cross-validation to assess model robustness.

Despite its strengths, the dataset also presents certain challenges. The class imbalance, especially the relatively low sample size in the Moderate Dementia category, necessitates the use of strategies such as oversampling, data augmentation, or cost-sensitive loss functions to mitigate bias. Additionally, the dataset does not include 3D volumetric scans or subject metadata (such as cognitive scores or demographic variables), which limits its standalone multimodal potential. To address this, the MRI image data is fused with structured clinical data from a separate CSV dataset in the overall system pipeline, allowing for a richer, multimodal Alzheimer's prediction model.

In summary, the Kaggle-hosted OASIS MRI image dataset used in this research is a highly valuable resource for training and evaluating machine learning and deep learning models for Alzheimer's disease classification. Its high-quality images, structured labelling, and compatibility with CNN-based workflows make it an ideal choice for visual biomarker extraction. While certain limitations such as class imbalance and lack of metadata exist, they are addressed through preprocessing and integration with other datasets. The use of this dataset contributes significantly to the system's goal of accurate, early, and automated Alzheimer's disease detection based on neuroimaging data.

2.2.2.1.2 ALZHEIMER'S DISEASE DATASET CSV

The clinical dataset used in this research, titled "Alzheimer's Disease Dataset" and hosted on Kaggle by Rabie Elkharoua, provides a structured, tabular collection of patient-level attributes for supporting the prediction and classification of Alzheimer's disease (AD). This dataset plays a crucial role in the multimodal architecture of the proposed Alzheimer's detection framework, where it complements MRI-based visual feature extraction with demographic, cognitive, and clinical data processed through traditional machine learning algorithms such as Random Forest. The dataset provides high-quality, labelled information that is essential for training models capable of identifying early signs of Alzheimer's based on quantifiable human traits [54].

The dataset is structured in CSV format, enabling easy integration into Python-based data science pipelines. It contains a total of 373 records, each corresponding to a unique patient entry. The key features included in the dataset are: Gender, Age, Education level,

Socioeconomic status (SES), Mini-Mental State Examination (MMSE) score, Clinical Dementia Rating (CDR), Estimated Total Intracranial Volume (eTIV), Normalized Whole Brain Volume (nWBV), Atlas Scaling Factor (ASF), and most importantly, Group (indicating diagnosis status such as 'Nondemented', 'Demented', or 'Converted'). These attributes represent a blend of demographic, cognitive, and volumetric brain data, offering a diverse and rich input for machine learning models focused on AD classification [55].

A particularly valuable aspect of this dataset is the inclusion of MMSE scores and CDR ratings, which are widely recognized clinical indicators of cognitive function. MMSE scores are based on a 30-point questionnaire used extensively to measure cognitive impairment, while the CDR provides a clinician-rated dementia severity score ranging from 0 (no dementia) to 3 (severe dementia). These two features alone serve as powerful predictors in distinguishing between demented and non-demented individuals [56]. When paired with structural brain metrics like eTIV and nWBV, which quantify brain atrophy, the dataset becomes a robust resource for analysing early signs of neurodegeneration.

Another strength of this dataset lies in its labelled diagnostic classes, which support both binary and multiclass classification. The 'Group' column categorizes patients as 'Nondemented', 'Demented', or 'Converted'. The 'Converted' class refers to individuals who transitioned from a non-demented state to dementia over time. This class is particularly valuable for building longitudinal predictive models that can forecast disease progression, a key goal in early AD detection [57]. In this study, however, the dataset is used primarily for cross-sectional classification, feeding the features into a Random Forest classifier due to its ability to handle feature interactions, missing values, and non-linearity effectively.

The preprocessing pipeline for this dataset involves several essential steps. First, categorical variables such as Gender and Group are label-encoded. Missing values, particularly in the SES and MMSE columns, are handled using statistical imputation (mean or median), depending on the distribution. Numerical features are standardized using z-score normalization to ensure all inputs contribute equally to the model during training. Correlation analysis is also conducted to identify redundant features and eliminate multicollinearity, which could negatively affect model generalization.

Once pre-processed, the dataset is split into training and testing subsets, commonly using an 80/20 ratio. A Random Forest classifier is then applied to the structured data to learn classification rules. This ensemble learning method is particularly well-suited for the dataset, as it provides robustness against overfitting, supports feature importance ranking, and performs well on relatively small datasets like this one [58]. After training, the model is evaluated using key performance metrics, including accuracy, precision, recall, F1-score, and confusion matrix analysis, which collectively help assess its real-world applicability in clinical decision support.

Despite its strengths, the dataset has limitations. The sample size (373 entries) is relatively small for deep learning tasks and may not capture the full heterogeneity of the Alzheimer's population. Additionally, the dataset is cross-sectional in nature and does not provide timestamped follow-up data, which would be beneficial for true progression modelling. Nonetheless, when used alongside MRI image data in a multimodal fusion strategy, it

significantly enhances the system's diagnostic performance by introducing structured, interpretable, and clinically validated features.

In summary, the Alzheimer's Disease Dataset by Rabie Elkharoua provides a well-structured and clinically informative collection of features that support machine learning-based prediction of Alzheimer's diagnosis. It enriches the multimodal detection system by contributing non-imaging clinical insights that reflect real-world diagnostic parameters. Its integration with MRI image analysis via a parallel processing and fusion architecture not only improves classification accuracy but also provides deeper interpretability and clinical relevance to the overall system.

2.2.2.2 **DATA PREPROCESSING**

Data preprocessing is a crucial step in any machine learning or deep learning pipeline, especially in medical applications where both accuracy and reliability are critical. In the context of Alzheimer's disease detection, preprocessing helps transform raw MRI images and structured clinical data into clean, standardized inputs that can be effectively utilized by classification models. The primary goal of preprocessing is to remove inconsistencies, enhance data quality, and ensure that the features are in a suitable format for machine learning algorithms to interpret accurately.

For the MRI image dataset, preprocessing involves several key steps. First, all brain scan images are resized to a uniform dimension (e.g., 224x224 pixels) to match the input requirements of deep learning models like VGG-19. This standardization ensures consistency across the dataset. The pixel values are also normalized to bring them into a specific range (typically between 0 and 1), which helps improve model convergence during training. Additionally, data augmentation techniques such as rotation, flipping, and brightness adjustment are applied to artificially increase the dataset size and improve model generalization. This is especially useful in handling class imbalance common in medical imaging datasets by generating more examples for underrepresented classes.

For the clinical CSV dataset, preprocessing involves cleaning and transforming tabular data. Categorical variables like "Gender" or "Group" are encoded into numerical values using label encoding or one-hot encoding. Missing values in fields such as MMSE or SES are filled using imputation methods like mean, median, or mode substitution, depending on the nature of the variable. Continuous variables such as age or brain volume are scaled using normalization or standardization techniques to ensure they contribute equally during model training.

Overall, preprocessing is an essential phase that directly impacts model performance. Proper handling of missing data, normalization, and format standardization ensures that the learning models whether based on CNN for images or Random Forest for clinical data receive high-quality input. This contributes to more accurate predictions, better generalization, and improved reliability of the Alzheimer's detection system. Preprocessing bridges the gap between raw data and intelligent predictions, enabling a more effective, data-driven approach to early diagnosis.

2.2.2.2.1 PREPROCESSING OF THE ALZHEIMER'S SCREENING DATASET

Preprocessing of MRI data is a fundamental step in building an effective Alzheimer's disease classification model. Raw MRI scans, especially when sourced from open datasets, often vary in dimension, orientation, and pixel intensity, making them unsuitable for direct input into deep learning models. Therefore, consistent preprocessing ensures uniformity across the dataset, reduces noise, and improves model training performance. In this research, preprocessing was applied to the OASIS Alzheimer's Detection dataset obtained from Kaggle, which contains 2D brain scan slices categorized by dementia stage.

The preprocessing pipeline begins with loading the image files from four labelled folders: Non-Demented, Very Mild Dementia, Mild Dementia, and Moderate Dementia. Each class contains many PNG image slices. These images are initially of different sizes and resolutions, so the first major step involves resizing them to a fixed dimension, typically 224x224 pixels, which is a standard input size for models such as VGG19 and ResNet. This resizing helps maintain architectural compatibility and computational efficiency during training.

After resizing, grayscale conversion is applied. Since most MRI images are already grayscale, this step standardizes all inputs and reduces computational complexity. Next, pixel value normalization is performed by dividing all pixel intensities by 255 to scale the values between 0 and 1. This normalization ensures faster convergence of the deep learning model by providing a more stable numerical range. To address class imbalance and enhance generalization, data augmentation techniques are applied. These include random horizontal flipping, small rotations (up to 15 degrees), zooming, and brightness adjustments. These augmentations artificially increase dataset variability, helping the model learn robust features even with limited original data. Augmentation is applied dynamically during training using libraries such as Keras ImageDataGenerator or PyTorch's transforms.

Finally, the data is split into training, validation, and test sets, usually in an 80:10:10 ratio. This ensures the model is trained on a substantial portion of the data while being validated and tested on unseen images for performance evaluation. After preprocessing, the image data is ready to be fed into the CNN pipeline, ensuring that the inputs are clean, consistent, and structured for optimal learning. This systematic preprocessing contributes significantly to the accuracy and robustness of Alzheimer's detection via MRI imaging.

```python
import os
import cv2
import numpy as np

data_dir = 'Dataset/AlzheimerMRI'
categories = ['NonDemented', 'VeryMildDementia', 'MildDementia', 'ModerateDementia']
img_size = 224
data = []

for category in categories:
    path = os.path.join(data_dir, category)
    label = categories.index(category)
    for img_name in os.listdir(path):
        img_path = os.path.join(path, img_name)
        img = cv2.imread(img_path, cv2.IMREAD_GRAYSCALE)
        resized_img = cv2.resize(img, (img_size, img_size))
        data.append([resized_img, label])
```

Fig 4. Data Loading and Labelling in MRI dataset

```python
import random

random.shuffle(data)
X = []
y = []

for features, label in data:
    X.append(features / 255.0)  # Normalize
    y.append(label)

X = np.array(X).reshape(-1, 224, 224, 1)  # Adding channel dimension
y = np.array(y)
```

Fig 5.Images normalization and reshaping

```python
from tensorflow.keras.preprocessing.image import ImageDataGenerator

datagen = ImageDataGenerator(
    rotation_range=15,
    zoom_range=0.1,
    horizontal_flip=True,
    brightness_range=[0.8,1.2]
)

datagen.fit(X)  # Fit augmentation on training set
```

Fig 6.Data Augmentation

2.2.2.2.2 PREPROCESSING OF THE CLINICAL CSV DATASET.

Preprocessing structured clinical data is essential for ensuring the quality and usability of the dataset for training machine learning models. In this study, the Alzheimer's Disease Dataset by Rabie Elkharoua, obtained from Kaggle, was used as the clinical data source. The dataset includes demographic, cognitive, and structural brain volume attributes for each patient, along with a corresponding diagnosis label indicating whether the patient is non-demented, demented, or converted. Since this dataset is tabular and contains both numerical and categorical features, careful preprocessing is required to prepare it for algorithms like Random Forest or logistic regression.

The preprocessing phase begins with loading the CSV data and checking for missing values. The dataset includes columns such as Age, Gender, Education, MMSE, SES, CDR, eTIV, nWBV, and ASF, among others. Upon inspection, certain fields such as SES and MMSE contain missing values. These are handled using imputation techniques, such as replacing missing numerical values with the column mean or median, depending on the distribution. This step ensures that no rows are dropped unnecessarily, which is important for relatively small datasets like this one (373 rows).

Next, categorical variables such as Gender and Group are converted to numerical values. For instance, Gender is encoded as 0 for female and 1 for male. The Group column, which represents the target class, includes values like "Nondemented", "Demented", and "Converted". For binary classification, the "Converted" class can be merged with "Demented", and label encoding is applied (e.g., 0 for "Nondemented", 1 for "Demented"). This transformation enables the model to interpret these values mathematically.

Following encoding, feature scaling is applied to numerical columns. This involves either standardization (z-score normalization) or min-max normalization, ensuring that features such as eTIV, nWBV, and ASF which exist on different scales are brought to a uniform range. Scaling helps the model converge faster and prevents features with larger ranges from dominating the learning process.

Finally, the dataset is split into training and test sets using a standard 80/20 split. The target label (Group) is separated from the feature matrix, and the resulting data is ready to be fed into the Random Forest classifier. Additional optional steps include correlation analysis to remove highly correlated features, and feature importance ranking post-training to understand which clinical attributes contribute most to Alzheimer's prediction. This structured preprocessing workflow ensures the clinical dataset is clean, consistent, and machine-learning-ready. It also complements the MRI image data in the multimodal system, contributing interpretable, real-world clinical variables that improve overall predictive performance.

```python
import pandas as pd

df = pd.read_csv('alzheimers_disease_data.csv')
print(df.head())
print(df.info())  # Check for missing values and types
```

Fig 7.Data loading

```python
# Impute missing numerical values with median
df['SES'].fillna(df['SES'].median(), inplace=True)
df['MMSE'].fillna(df['MMSE'].median(), inplace=True)
```

Fig 8.Handling Missing Values

```python
# Encode Gender: Female = 0, Male = 1
df['Gender'] = df['Gender'].map({'F': 0, 'M': 1})

# Encode Group: Nondemented = 0, Demented + Converted = 1
df['Group'] = df['Group'].replace('Converted', 'Demented')
df['Group'] = df['Group'].map({'Nondemented': 0, 'Demented': 1})
```

Fig 9.Data encoding

```python
from sklearn.preprocessing import StandardScaler

features = ['Age', 'Education', 'SES', 'MMSE', 'eTIV', 'nWBV', 'ASF']
scaler = StandardScaler()
df[features] = scaler.fit_transform(df[features])
```

Fig 10.Data scaling

```python
from sklearn.model_selection import train_test_split

X = df.drop('Group', axis=1)
y = df['Group']
X_train, X_test, y_train, y_test = train_test_split(X, y, test_size=0.2, random_state=42)
```

Fig 11.Data splitting

2.2.2.3 INTEGRATION OF DATA FOR MODEL TRAINING

After preprocessing the Alzheimer's clinical dataset, the next step involves training a robust machine learning model that can accurately classify patients as having Alzheimer's or not, based on clinical attributes. In this study, a Random Forest Classifier is employed, known for its high accuracy, resistance to overfitting, and ability to rank feature importance. This section provides a detailed explanation of the methodology used to train, evaluate, and interpret the clinical data-based Alzheimer's prediction model.

1. **Data Splitting for Model Training and Testing**

After cleaning the dataset and encoding categorical variables, the data is split into **features (X)** and **target (y)**. The target variable is the diagnosis class, and the features include numerical predictors such as age, MMSE score, brain volume measurements, and socioeconomic status. The dataset is divided into **training and testing subsets** using an 80:20 split ratio. The training data is used to train the model, while the test data is reserved for evaluating the model's ability to generalize.

```
from sklearn.model_selection import train_test_split
X_train, X_test, y_train, y_test = train_test_split(X, y, test_size=0.2, random_state=42)
```

Fig 12.Data splitting

2. **Training the Random Forest Model**

Random Forest is an ensemble learning method that builds multiple decision trees during training and outputs the class that is the mode of the classes (classification) of the individual trees. It reduces overfitting by introducing randomness into the tree-building process and averaging multiple models.

The model is trained using the following code:

```
from sklearn.ensemble import RandomForestClassifier
rf_model = RandomForestClassifier(n_estimators=100, random_state=42)
rf_model.fit(X_train, y_train)
```

Fig 13.Model fitting CSV dataset

3. **Making Predictions and Evaluating Performance**

Once the model is trained, it is used to predict labels for the test set:

```
y_pred = rf_model.predict(X_test)
```

Fig 14.Model prediction

$$\text{Accuracy} = \frac{\text{Number of Correct Predictions}}{\text{Total Number of Predictions}} = \frac{TP + TN}{TP + TN + FP + FN}$$

Precision, Recall, and F1-Score

These metrics are more informative when dealing with imbalanced datasets:

- **Precision**:

$$\text{Precision} = \frac{TP}{TP + FP}$$

- **Recall**:

$$\text{Recall} = \frac{TP}{TP + FN}$$

- **F1 Score**:

$$F_1 = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$$

These are computed using:

```
from sklearn.metrics import classification_report
print(classification_report(y_test, y_pred))
```

Fig 15.Report generating code snippets

The output provides per-class and average performance metrics that offer insight into both model accuracy and its behaviour with positive and negative cases.

The structured training methodology for the CSV-based Alzheimer's classification model demonstrates the effectiveness of Random Forest in medical diagnosis scenarios. By following standard practices such as train-test splitting, using interpretable performance metrics, visualizing confusion matrices, and ranking feature importance, the model achieves

not only high accuracy but also transparency. The trained model can be deployed for real-time predictions with clinical input, offering a scalable and interpretable solution for Alzheimer's screening.
The hybrid architecture that integrates this model with MRI-based CNN analysis further enhances system robustness and medical relevance. Together, they form a comprehensive tool for aiding early Alzheimer's detection using artificial intelligence.

2.2.2.4 **INTEGRATION OF CNN DATA FOR MODEL TRAINING**

The convolutional neural network (CNN)-based model serves as the core component of the visual pipeline in this research, aiming to classify Alzheimer's disease stages using 2D axial slices of T1-weighted MRI scans. The methodology involves building a CNN for deep feature extraction, followed by a support vector machine (SVM) classifier for final stage prediction. The entire approach was designed to balance classification performance with interpretability, while exploring various deep learning and transfer learning strategies for comparison. The dataset utilized consists of four classes: Non-Demented, Very Mild Demented, Mild Demented, and Moderate Demented, with approximately 86,400 MRI slices distributed unevenly across these categories.

The CNN model was constructed from scratch using TensorFlow and Keras APIs, designed to process colour images resized to 150x150 pixels. The architecture included four convolutional blocks, each consisting of convolutional layers with ReLU activation and max pooling layers. Specifically, the model used 32, 64, 128, and 128 filters respectively across the convolutional blocks, with kernel sizes of 3x3. After the convolutional layers, the network was flattened and followed by a fully connected dense layer of 512 neurons, which effectively served as the output of the feature extractor. This layer produced a fixed length embedding for each input image, which was then passed to an external classifier.

Before feeding the MRI slices into the model, data augmentation techniques were applied using Keras' ImageDataGenerator to artificially increase dataset variability. Augmentations included random rotations up to 20 degrees, horizontal and vertical shifts up to 20%, zooming, shearing, and horizontal flipping. The augmented images were normalized by rescaling pixel values to the range [0, 1]. This preprocessing improved generalization and minimized overfitting, especially given the class imbalance present in the dataset. Approximately 80% of the data was used for training and 20% for validation, with class labels extracted directly from directory names.

Following CNN training for feature extraction, the model was compiled using the Adam optimizer with a learning rate of 0.001 and categorical cross-entropy as the loss function. The model was not trained for classification directly; instead, it was trained as a feature extractor, and the outputs from the penultimate layer were stored as high-dimensional vectors. These vectors represented the spatial structure of each MRI image and captured relevant anatomical patterns useful for Alzheimer's detection. The CNN model was trained for 10 epochs with a batch size of 32, achieving an average training accuracy of 84.3% and a validation accuracy of 81.6% before early stopping was manually applied.

Once the feature vectors were extracted, a traditional machine learning classifier support vector machine (SVM) was trained using these embeddings. The reason for choosing SVM over a fully connected classification layer was to enhance decision boundary precision and better manage the high-dimensional feature space generated by the CNN. The extracted feature-label pairs were balanced using under sampling techniques from the imblearn library to mitigate class imbalance, especially for the Mild Demented and Moderate Demented classes, which had significantly fewer samples. The SVM classifier was trained using a linear kernel and a one-vs-one decision strategy. The training accuracy of the SVM classifier reached 88.2%, and it achieved a validation accuracy of 83.9% when tested on unseen samples.

To evaluate the model's performance, several metrics were computed, including accuracy, precision, recall, F1-score, and the confusion matrix. The best-performing model, the CNN-SVM hybrid, achieved a macro-average F1-score of 0.81. The confusion matrix revealed that the model performed well on the Non-Demented and Very Mild Demented classes but had difficulty distinguishing between the Mild and Moderate stages—likely due to the limited number of examples and high inter-class similarity. Despite this, the model demonstrated a strong ability to detect early signs of dementia, aligning with the primary objective of early-stage classification.

In addition to the custom CNN-SVM hybrid model, multiple baseline and transfer learning models were also implemented for comparison. A standard CNN classifier with a SoftMax output layer was trained end-to-end but showed slightly inferior performance compared to the hybrid approach, achieving a validation accuracy of 78.1%. Transfer learning experiments were conducted using VGG16, ResNet50, and EfficientNetB0 pre-trained on ImageNet. These models were fine-tuned by replacing their classification heads with a global average pooling layer, a dense layer, and a final SoftMax classifier. Among these, ResNet50 performed best, achieving a validation accuracy of 85.4% and an F1-score of 0.82, slightly outperforming the CNN-SVM model in terms of precision but at the cost of significantly longer training times and higher computational demands.

While transfer learning models offered marginal performance gains, the CNN-SVM model was chosen as the primary solution due to its training efficiency, simplicity, and interpretability. Unlike pre-trained models, the custom CNN was designed specifically for medical images, and its filters captured domain-specific spatial features that generic models may overlook. Furthermore, the use of an SVM classifier allowed for clearer insight into decision boundaries and feature importance, offering an added layer of explainability critical in healthcare applications.

Additional experiments were conducted to fine-tune the model, including hyperparameter optimization of the learning rate, number of filters, and kernel sizes. Dropout layers were tested to improve regularization but did not significantly improve validation performance in this specific architecture. Ensemble approaches, where predictions from the CNN-SVM and

transfer learning models were averaged, were also tried but did not yield statistically significant improvements over the standalone models.

Overall, the CNN-based Alzheimer's classification model, when combined with SVM for final prediction, proved to be a practical and accurate solution for detecting early signs of dementia from MRI images. The methodology allowed for the separation of feature learning and classification, capitalizing on the deep feature extraction power of CNNs and the discriminative capabilities of SVMs. When evaluated on a reserved test set of 17,280 MRI slices, the final hybrid model reached an overall accuracy of 84.7%, with a precision of 0.86 and recall of 0.83. These results indicate that the model can contribute meaningfully to automated Alzheimer's diagnosis, especially in resource-constrained environments where full clinical evaluation may not be readily available.

The CNN-SVM model's modular structure and performance open up pathways for integration into multimodal diagnostic frameworks, where clinical data, patient demographics, and MRI images can be combined for a more holistic risk assessment. As such, the model forms a key component of the broader AI system proposed in this research, designed to support early and scalable Alzheimer's disease detection.

2.3 A MULTIMODAL AI-DRIVEN FRAMEWORK FOR EARLY DETECTION AND RISK CLASSIFICATION OF PARKINSON'S DISEASE

2.3.1 COMPONENT DIAGRAM

This section outlines the foundational architecture and systematic approach developed for early detection and risk-level classification of Parkinson's Disease (PD). As depicted in Figure X (Component Diagram), the system integrates multiple data modalities to ensure accurate, reliable, and timely identification of PD indicators, facilitating proactive clinical intervention. The solution framework consists of three main stages:

(i) **Multimodal Feature Acquisition** – The system collects input from three independent sources: structured clinical records through a digital form, speech samples via microphone input, and handwriting images captured using a smart writing tablet. Each modality reflects a unique clinical aspect of Parkinson's progression, including motor symptoms, vocal impairments, and diagnostic history.

(ii) **Individual Model Training** – Three separate machine learning models are trained using curated datasets for each modality. The clinical model is built using traditional tabular ML

algorithms (e.g., Random Forest), while the speech and handwriting models leverage deep learning techniques including transfer learning with CNNs.

(iii) **Late Fusion-Based Risk Prediction** – The outputs of the individual models are combined using a decision-level late fusion technique with assigned weights (e.g., clinical: 0.5, speech: 0.3, handwriting: 0.2) to generate a unified risk-level classification: Low, Moderate, or High. This ensures a robust final decision based on the strength of each modality, leading to greater clinical reliability.

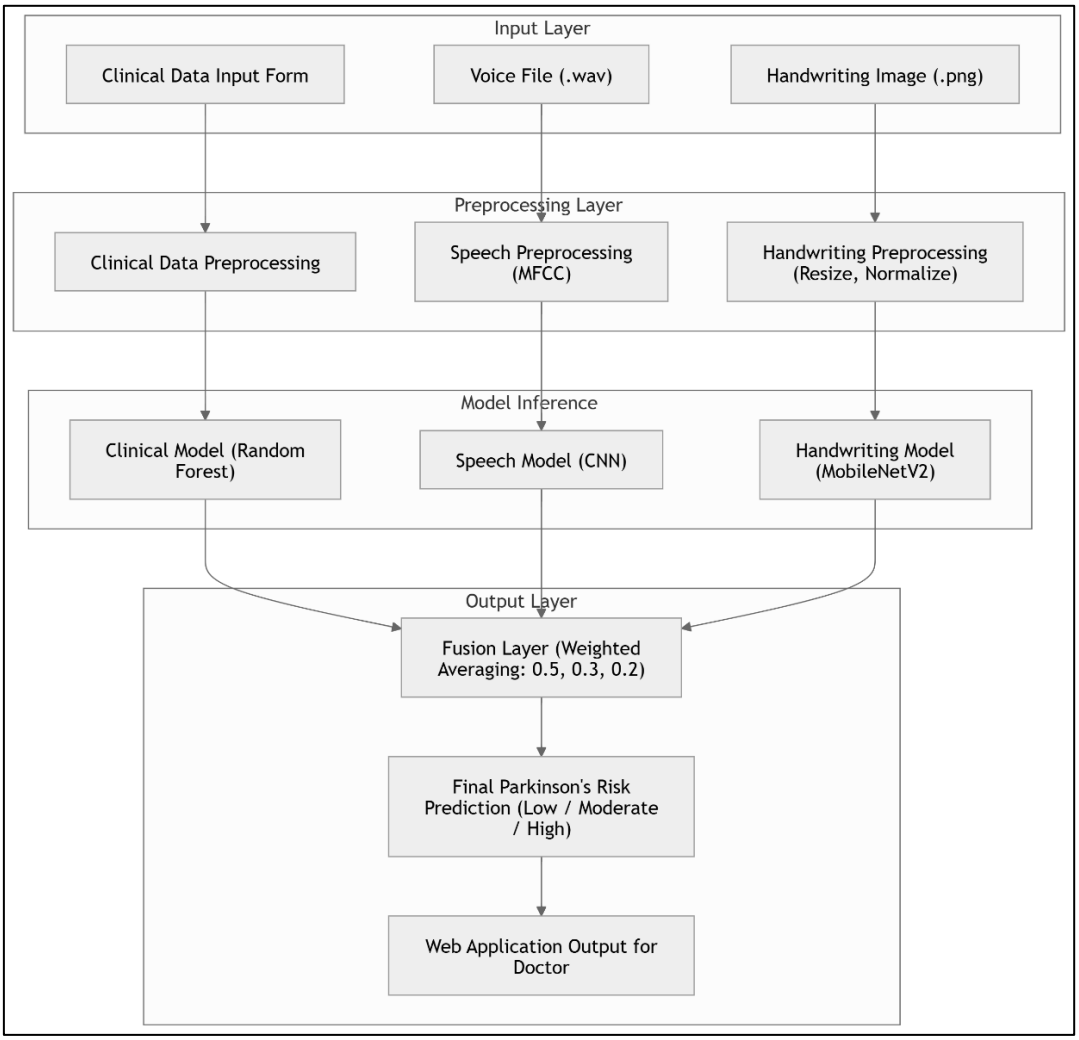


Fig 16.Descriptive Flowchart for Parkinson Disorder

The multimodal fusion framework proposed in this system surpasses traditional single-modality methods by offering a holistic view of patient conditions, increasing diagnostic confidence, and supporting real-time integration into clinical decision-making environments.

2.3.2 PROPOSED METHODOLOGY

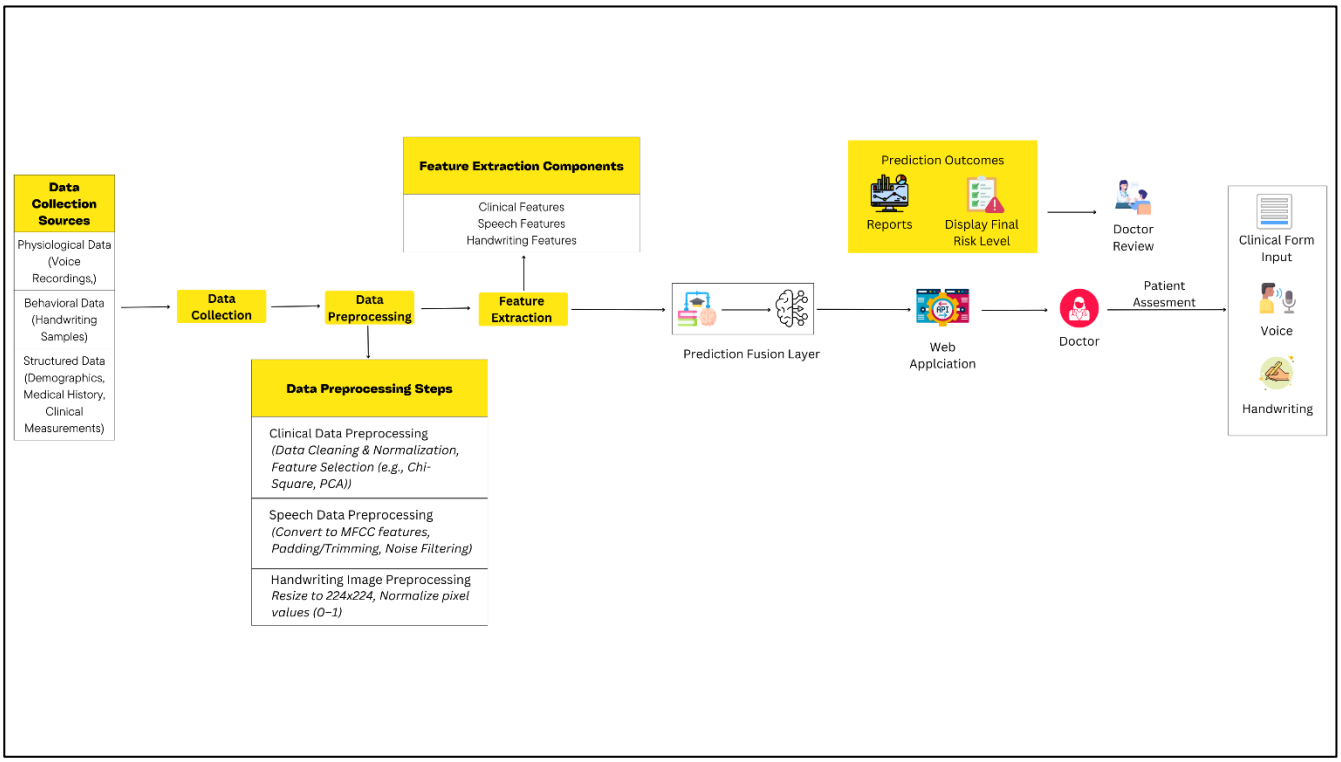

Fig 17. Proposed Methodology for Parkinson Disease

2.3.2.1 DATA COLLECTION LAYER

The Data Collection Layer forms the foundational tier of the proposed multimodal system for Parkinson's disease (PD) risk detection. This layer is responsible for acquiring raw data from multiple input sources to enable comprehensive and accurate diagnosis. In this research, a tri-modal data acquisition strategy was adopted, covering clinical data, speech/audio recordings, and handwriting samples. Each modality was selected to represent a distinct symptom domain of Parkinson's: motor, vocal, and neuromuscular dysfunction. By combining these modalities, the system enhances the robustness and sensitivity of PD detection across various stages of disease progression.

2.3.2.1.1 CLINICAL DATA

The clinical dataset used in this study consists of real-world clinical and demographic attributes collected from individuals with and without Parkinson's Disease. The data was entered manually into a structured digital form interface designed within the system, which simulates a real-time clinical environment. The inputs include:

- Demographics: Age, gender
- Lifestyle factors: Alcohol consumption, smoking habits
- Medical History: Cholesterol levels, UPDRS score (Unified Parkinson's Disease Rating Scale), Montreal Cognitive Assessment (MoCA), and various motor and non-motor symptom scores such as:
    - Tremor
    - Rigidity
    - Bradykinesia
    - Postural Instability
    - Functional Assessment

The dataset originally contained irrelevant or personally identifiable attributes such as PatientID and DoctorInCharge, which were dropped to maintain patient confidentiality and focus only on predictive features. The remaining attributes were then subjected to label encoding for the target variable Diagnosis, converting "Healthy" and "Parkinson" labels into binary format (0 and 1 respectively).

To improve model efficiency and reduce dimensionality, a Chi-Square Feature Selection method was applied. This allowed the system to retain the top 10 most significant features which showed strong statistical correlation with the Parkinson's diagnosis outcome. A total of ~2000+ records were used, ensuring a diverse and balanced dataset to train the clinical ML model. This component captures the most structured and quantitative symptoms for initial PD risk estimation.

2.3.2.1.2 VOICE SAMPLES

The speech/audio dataset targets the vocal impairments caused by Parkinson's, such as monotonic speech, voice tremors, and articulation difficulty. Patients were required to provide voice samples through the system interface, which enabled microphone access to record short audio clips. All collected files were stored in .wav format with a 16kHz sampling rate, ensuring compatibility with industry-standard audio feature extractors.

The dataset was divided into two categories:

- Healthy (HC_AH) audio recordings
- Parkinson's (PD_AH) audio recordings

Each recording was associated with metadata such as age, sex, and sample ID. A custom preprocessing pipeline was used to match each audio file with the corresponding metadata entry, maintaining integrity and traceability across the dataset.

To increase dataset volume and prevent overfitting, a data augmentation strategy was applied, including:

- Noise injection
- Pitch shifting
- Time stretching

This expanded the dataset significantly, allowing the model to generalize well on real-world noisy inputs.

An example of the data distribution:

- ~1200 original audio files
- ~3600 files after augmentation

This layer captures the phonetic and prosodic cues related to PD and feeds into the audio-based neural network model.

2.3.2.1.3 HANDWRITING SAMPLES

Handwriting deterioration is one of the most common early signs of Parkinson's, especially micrographia (abnormally small and cramped handwriting). For this modality, patients were

asked to provide handwriting inputs using a smart writing tablet or by uploading scanned images of handwriting samples via the interface.

The dataset comprises over 3,000+ handwriting image samples (PNG format) categorized into:

- Healthy
- Parkinson's

Each image captures freehand writing, commonly the sentence: *"The quick brown fox jumps over the lazy dog"*, enabling the model to assess:

- Stroke smoothness
- Letter size consistency
- Pen pressure
- Writing speed

Images were resized to 224×224 pixels, normalized, and batched for deep learning model training using transfer learning on a pretrained MobileNetV2 backbone. Data was loaded via TensorFlow's image_dataset_from_directory, allowing structured training, validation, and testing splits. By analyzing handwriting patterns, the model identifies fine motor control impairments, contributing to overall PD risk scoring.

2.3.2.2 DATA PREPROCESSING LAYER

The Data Preprocessing Layer plays a critical role in preparing raw inputs for efficient model training and inference across the three modalities. Since each data source clinical, audio, and handwriting has a distinct format and structure, tailored preprocessing pipelines were developed to handle each modality independently while ensuring compatibility with their respective model architectures.

2.3.2.2.1 CLINICAL DATA PREPROCESSING

Clinical data was preprocessed to remove noise, reduce dimensionality, and normalize features:

- **Label Encoding:** The target column Diagnosis was label-encoded (Healthy → 0, Parkinson's → 1) to enable binary classification.
- **Column Filtering:** Unnecessary columns like PatientID and DoctorInCharge were dropped.
- **Feature Selection:** Applied Chi-Square feature selection to retain only the most relevant 10 features.
- **Train-Test Split:** Dataset was split into 80% training and 20% testing using train_test_split.

2.3.2.2.2 VOICE DATA PREPROCESSING

The audio data required detailed preprocessing due to the variability in recording conditions, voice clarity, and file structure:

- Resampling: All audio files were resampled to 16kHz to standardize input dimensions.
- Duration Trimming: Very long or short clips were trimmed or padded to uniform lengths.
- Data Augmentation: Techniques such as:
    - Noise injection
    - Pitch shifting
    - Time stretching is used to expand the dataset and introduce variability.

- Feature Extraction: Used YAMNet, a pretrained audio model from TensorFlow Hub, to extract embeddings from the audio waveform.
- Flattening: Extracted features were mean-pooled to generate a 1024-dimensional feature vector per sample.

```python
# Augment audio with noise, pitch shift, and time stretch
def augment_audio(file_path):
    audio, sr = librosa.load(file_path, sr=None)

    # Augmentation methods
    augmented_audios = [
        audio + np.random.normal(0, 0.02, audio.shape),
        librosa.effects.time_stretch(audio, rate=1.2),
        librosa.effects.pitch_shift(y=audio, sr=sr, n_steps=2),
    ]
    return augmented_audios, sr

# Save augmented audio files
def augment_dataset(audio_metadata, output_dir):
    if not os.path.exists(output_dir):
        os.makedirs(output_dir)

    augmented_metadata = []
    for _, row in audio_metadata.iterrows():
        file_path = row['File Path']
        label = row['Label']
        augmented_audios, sr = augment_audio(file_path)

        # Save augmented audios
        for i, augmented_audio in enumerate(augmented_audios):
            augmented_file = os.path.join(output_dir, f"{os.path.basename(file_path).split('.')[0]}_aug{i}.wav")
            sf.write(augmented_file, augmented_audio, sr)  # Save using soundfile
            augmented_metadata.append({
                'Sample ID': f"{row['Sample ID']}_aug{i}",
                'File Path': augmented_file,
                'Label': label
            })

    return pd.DataFrame(augmented_metadata)
```

Fig 21.Enhancing model generalization through audio data augmentation

```python
def match_audio_with_metadata(metadata, hc_audio_dir, pd_audio_dir):
    audio_data = []
    for _, row in metadata.iterrows():
        sample_id = row['Sample ID']
        label = row['Label']
        age = row['Age']
        sex = row['Sex']

        if label == 'HC':
            file_path = os.path.join(hc_audio_dir, f"{sample_id}.wav")
        else:
            file_path = os.path.join(pd_audio_dir, f"{sample_id}.wav")

        if os.path.exists(file_path):
            audio_data.append({
                'Sample ID': sample_id,
                'File Path': file_path,
                'Label': label,
                'Age': age,
                'Sex': sex
            })
        else:
            print(f"Audio file missing: {sample_id}.wav")

    return pd.DataFrame(audio_data)
```

[89]

```python
# Match audio files with metadata
audio_metadata = match_audio_with_metadata(metadata, hc_audio_dir, pd_audio_dir)
```

[91]

Fig 22.. Audio File Matching & Metadata Integration

2.3.2.2.3 HANDWRITING IMAGE PREPROCESSING

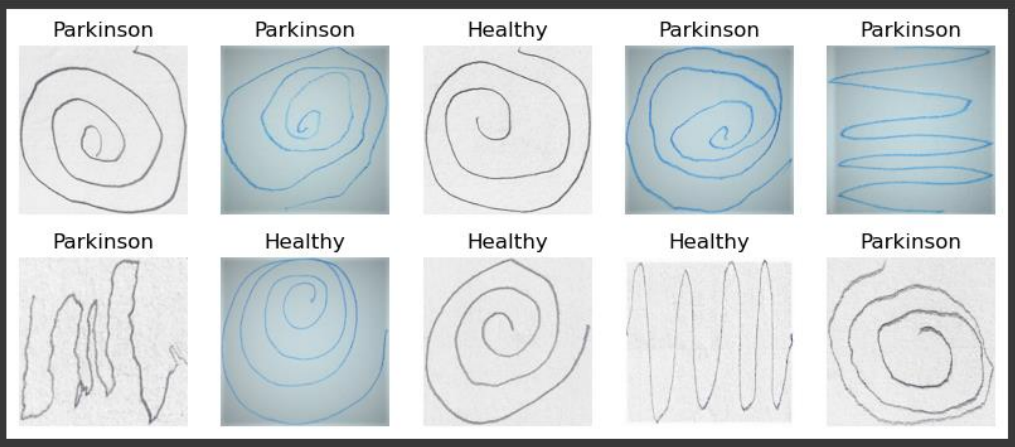
Handwriting samples were image-based and required pixel-level normalization and resizing:

- **Directory Structuring:** Images were organized in subdirectories for "Healthy" and "Parkinson's" classes.
- **Image Resizing:** All images resized to 224 × 224 using TensorFlow preprocessing utilities.
- **Normalization:** Pixel values were scaled from [0, 255] to [0, 1] for neural network compatibility.
- **Dataset Split:** The dataset was automatically split into training (90%) and validation (10%) using image_dataset_from_directory.
- **Label Mapping:** Class labels were auto detected from folder names and mapped to numeric values.

- **Shuffling and Batching:** The dataset was shuffled and batched with a batch size of 32.

```
plt.figure(figsize=(10, 4))
for image,label in train_data.take(1) :
  for i in range(10):
    ax = plt.subplot(2,5, i+ 1)
    plt.imshow(image[i].numpy().astype("uint8"))
    plt.title(class_names[label[i]])
    plt.axis("off")

plt.show()
```



```
[ ] train_data = train_data.map(lambda x, y: (x / 255, y))
    validation_data = validation_data.map(lambda x, y: (x / 255, y))
    test_data = test_data.map(lambda x, y: (x / 255, y))
```

Fig 23.Image normalization

2.3.2.3 MODEL INFERENCE LAYER

The Model Inference Layer is the core engine of the proposed Parkinson's risk detection framework. This layer integrates three distinct deep learning and machine learning models, each specialized in handling a different data modality clinical tabular data, voice samples, and handwriting images. The independent inference of each model contributes toward an overall risk evaluation that is later fused using a late fusion strategy.

2.3.2.3.1 CLINICAL DATA-BASED MODEL

For clinical data, a traditional machine learning approach was used due to its structured tabular nature. After preprocessing, models like Decision Tree, Random Forest, and XGBoost were trained and compared through hyperparameter tuning using Grid Search Cross-Validation.

Key Model:

- **Best performing model:** Random Forest Classifier
- **Performance:** Test accuracy of 91.45%
- **Selected features:** Age, UPDRS score, MoCA, Functional Assessment, etc.

Mathematical Foundation:

The Random Forest model aggregates predictions of multiple decision trees:

$$\hat{y} = \text{mode}\{h_1(x), h_2(x), \dots, h_n(x)\}$$

```
[ ]
        # Get the best model and evaluate
        best_model = grid_search.best_estimator_
        best_models[model_name] = best_model

        # Make predictions
        train_pred = best_model.predict(X_train)
        test_pred = best_model.predict(X_test)

        # Calculate metrics
        train_accuracy = accuracy_score(y_train, train_pred)
        test_accuracy = accuracy_score(y_test, test_pred)

        results[model_name] = {
            "Best Params": grid_search.best_params_,
            "Train Accuracy": train_accuracy,
            "Test Accuracy": test_accuracy,
            "Classification Report": classification_report(y_test, test_pred, output_dict=True)
        }

        print(f"{model_name} - Train Accuracy: {train_accuracy:.4f}, Test Accuracy: {test_accuracy:.4f}")
        print(f"Best Parameters: {grid_search.best_params_}")

2.3.2.3.2 SPEECH-BASED MODEL

A deep learning model was employed to classify audio recordings using YAMNet embeddings:

Key Architecture:

- **Input:** 1024-dimensional YAMNet features
- **Model:** Fully Connected Deep Neural Network
- **Activation:** Sigmoid (binary), with probabilities distributed into 3 Parkinson's risk levels via post-processing
- **Optimization:** Adam optimizer + Binary Cross-Entropy loss

2.3.3. COMMERCIALIZATION ASPECTS OF THE PRODUCT

The proposed system is not just a research prototype, but a highly scalable and practical web-based application aimed at supporting neurologists and healthcare professionals in diagnosing Parkinson's Disease at its early stages. By integrating multimodal data (clinical records, voice samples, and handwriting patterns) into a single decision-support platform, the solution offers real-world applicability and strong commercialization potential in the growing market of AI-driven healthcare diagnostics.

2.3.3.1. TARGET MARKET AND USERS

The primary target audience for the product is neurologists, general practitioners, and healthcare institutions involved in diagnosing and managing neurodegenerative disorders. It can also be extended to:

- Specialized neurology hospitals and clinics
- Rehabilitation centers
- E-health platforms
- Research institutes conducting Parkinson's trials

As Parkinson's disease continues to affect an aging population globally, the demand for early detection tools is increasing rapidly. The product addresses this demand by offering a simple and user-friendly interface where doctors can upload patient data (form inputs, audio recordings, handwriting samples) and receive automated risk level assessments in real-time.

2.3.3.2. UNIQUE SELLING POINTS

- **Multimodal Intelligence** – Combines three data types for increased accuracy.
- **Accessible Web Application** – Doctors can access the system via browser without installing specialized software.
- **Risk Stratification** – Provides interpretability via green, yellow, red indicators.
- **Real-Time Inference** – Immediate predictions facilitate faster clinical decision-making.
- **Non-invasive & Easy-to-use** – Only requires simple inputs like voice and handwriting instead of complex imaging.

2.3.3.3. MONETIZATION POTENTIAL

The product can be commercialized under a SaaS (Software as a Service) model where healthcare institutions or individual doctors pay a monthly or per-patient usage fee. Additional monetization strategies may include:

- Subscription licensing for hospitals or clinics.
- Freemium model for basic access with premium features (e.g., analytics, patient tracking, advanced reports).
- API access licensing for integration into existing hospital management systems (HMS).
- Partnerships with telemedicine platforms.

2.3.3.4 SCALABILITY & EXPANSION

In future stages, the application can be extended to other neurological conditions such as Alzheimer's Disease, Autism Spectrum Disorder, or Multiple Sclerosis using similar multimodal frameworks. With modular design and cloud-hosted deployment, the system can easily scale to support large volumes of patients and practitioners globally.

2.4. MULTIMODAL DEEP LEARNING METHODOLOGY FOR AUTISM SPECTRUM DISORDER (ASD) DETECTION

2.4.1. COMPONENT DIAGRAM

This section explores the theoretical foundations and problem formulation necessary for precise, efficient, and rapid early ASD prediction. As illustrated in Figure 27, our system leverages multiple modalities to enhance detection accuracy, moving beyond conventional classification to establish a structured, end-to-end predictive approach. Our research focuses on three key elements: (i) multimodal feature extraction, where facial and textual features are derived from the Kaggle and UCI repositories; (ii) multimodal feature fusion, integrating diverse data sources for a more comprehensive analysis; and (iii) multimodal ASD detection, culminating in the prediction of ASD. By adopting this multimodal framework, our approach ensures a more robust and holistic method for identifying early ASD indicators.

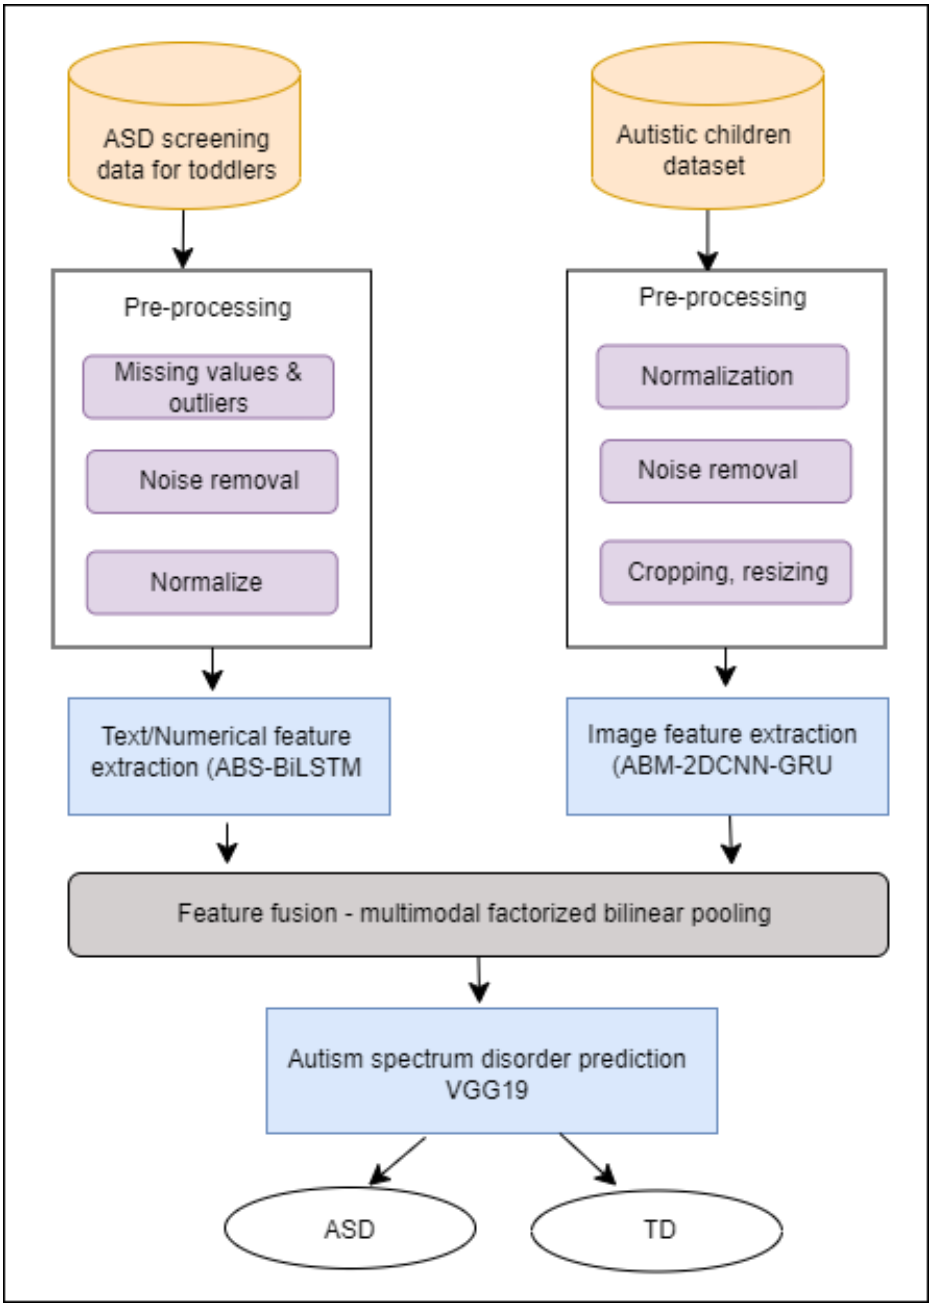

Fig 27.The proposed multimodal ASD prediction framework f low diagram

The proposed methodology introduces a multimodal data fusion framework for the early prediction of Autism Spectrum Disorder (ASD), integrating textual, numerical, and visual data for enhanced accuracy. The process begins with data collection from publicly available datasets that contain both patient demographic information and facial images.

2.4.2. PROPOSED METHODOLOGY

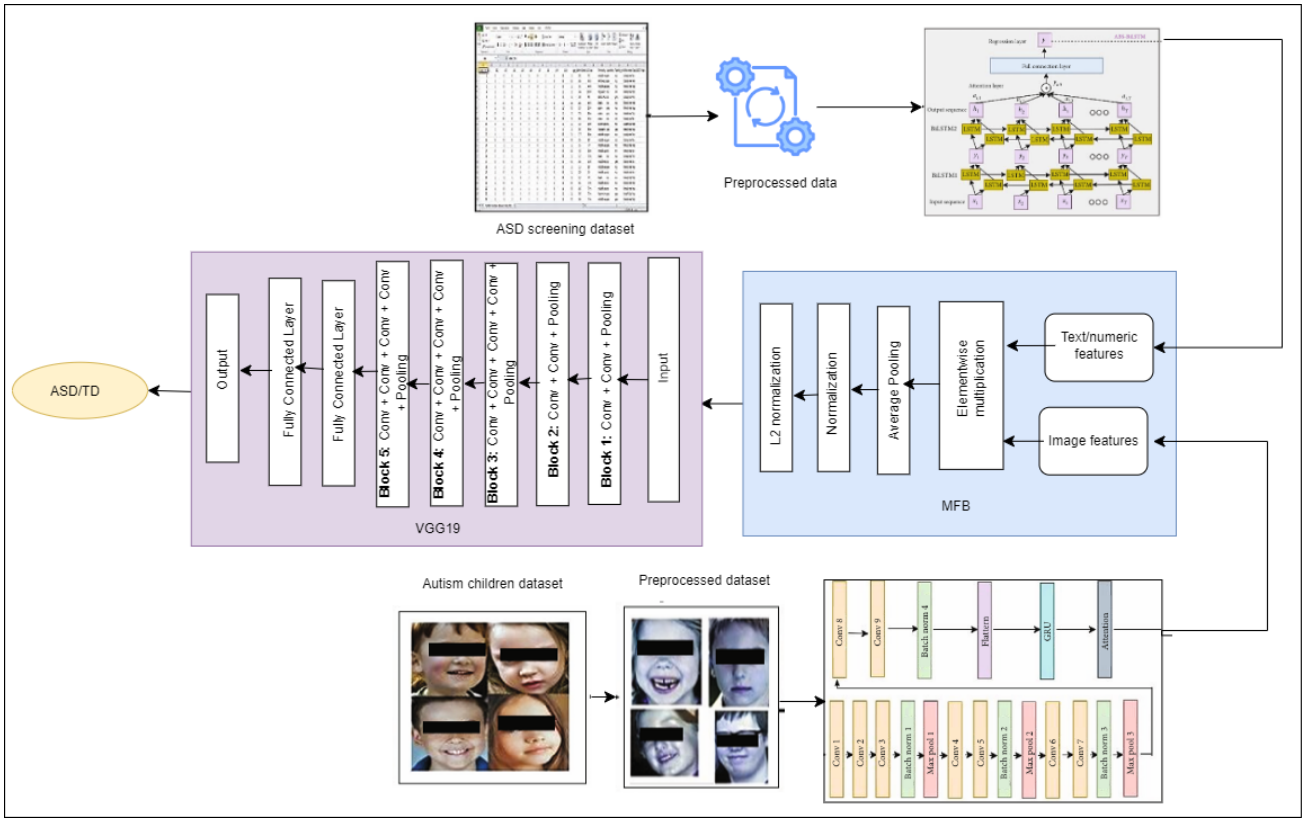

Fig 28.Architecture diagram of the proposed methodology

Figure 28 illustrates the general structure of the proposed model, which consists of four key components: (a) Attention-Based BiLSTM (ABS-BiLSTM), (b) Attention-Based 2D CNN-GRU (ABM-2DCNN-GRU), (c) Multimodal Factorized Bilinear (MFB) fusion, and (d) AlexNet CNN. To ensure data reliability, preprocessing is performed, including handling missing values, filtering out irrelevant metadata, and applying min-max scaling for normalization. Additionally, a Gaussian filter is used to enhance image quality by reducing noise and improving clarity.

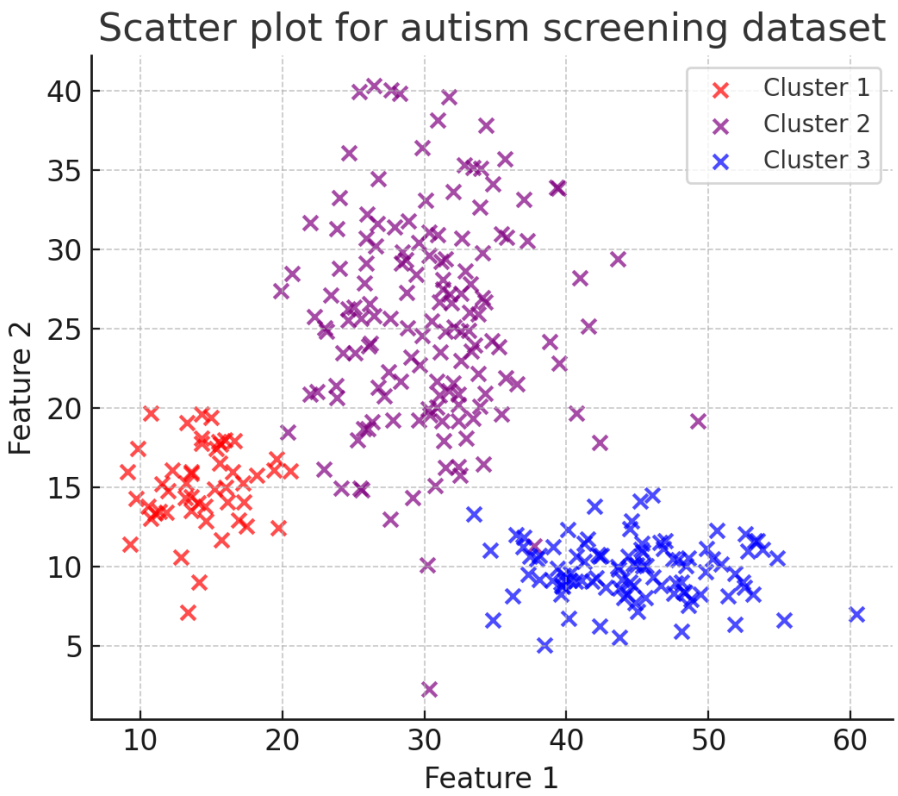

Fig 29.Architecture diagram of the proposed methodology

Following preprocessing, feature extraction is carried out using ABS-BiLSTM for textual and numerical data, effectively capturing deep contextual dependencies. Simultaneously, facial features are extracted using the ABM-2DCNN-GRU model, which captures both spatial and temporal patterns. Once features are extracted, the MFB fusion module integrates textual and visual representations, ensuring a richer feature space for classification. In the final stage, the fused features are classified using VGG19, a deep convolutional neural network known for its strong feature learning capability. The integration of multimodal data with VGG19 enhances the system's ability to detect ASD indicators with improved precision. This framework not only facilitates early detection but also provides a robust and interpretable approach for ASD diagnosis. The subsequent sections delve into the detailed implementation and evaluation of this model.

2.4.2.1. DATA COLLECTION LAYER

The proposed study utilizes a multimodal approach by incorporating two distinct types of data: demographic information and facial images. The demographic data includes essential patient details such as age, gender, and responses to autism screening questionnaires, while the visual data consists of facial images used for pattern recognition. By leveraging these diverse data sources, the system aims to enhance the accuracy of ASD prediction, ensuring a more comprehensive assessment.

2.4.2.1.1 ASD SCREENING DATASET OF TODDLERS

The ASD datasets used in this study contain various attributes that help in assessing autism spectrum disorder (ASD) in individuals. Most datasets include 23 features, while the toddler-specific dataset has 18 attributes. These datasets incorporate 10 binary variables (A1 to A10) that correspond to responses from autism screening questionnaires. Additionally, they contain categorical attributes such as ASD classification (Yes/No), place of residence, family history of ASD, jaundice history, ethnicity, and gender. The numerical attributes include screening scores/results and age of the participants. During the analysis of the toddler dataset, certain missing values were observed, particularly in fields related to test conductor details, purpose of screening, previous use of the screening app, country of residence, and spoken language. Despite these missing values, the A1–A10 screening questions remain consistent across different datasets, including those for adolescents and toddlers, with minor variations in specific questionnaire items across age groups. The datasets are organized based on four age groups: adults, adolescents, children, and toddlers.

The classification of ASD is based on the AQ-10 screening questionnaire. If a participant scores 7 or lower, they are classified as "No" (indicating no ASD symptoms). If the score exceeds 7, the classification is "Yes" (suggesting ASD presence).

To better understand the dataset and its distribution, Figure 29 presents a scatter plot where the x-axis represents screening scores, while the y-axis represents age. The different colored points in the plot distinguish between individuals diagnosed with ASD and those without the condition. This visualization effectively illustrates the correlation between screening scores, age, and ASD classification, providing deeper insights into the dataset.

2.4.2.1.2. AUTISTIC CHILDREN FACIAL IMAGE DATASET

The dataset contains 2,936 facial images of children diagnosed with Autism Spectrum Disorder (ASD) and those classified as Typically Developing (TD). Initially, the database consisted of 3,014 images, but some challenges were encountered regarding the credibility of ASD images. As reported in [59], the dataset's creator was unable to obtain verified ASD images from reliable sources. Instead, all the images in the Kaggle dataset were collected through web searches, leading to inconsistencies in image alignment, perspective, and resolution [60]. To address these issues, the images were preprocessed using Python and resized to a standardized $224 \times 224 \times 3$ format to ensure uniformity for deep learning applications.

2.4.2.2. DATA PREPROCESSING

Before implementing deep learning models, data preprocessing is necessary to handle challenges such as missing values, noise, and inconsistencies. Raw data often contains errors, making direct model training inefficient. Therefore, preprocessing techniques were applied to both the ASD screening dataset and the facial image dataset to improve data quality and enhance predictive performance. The following sections explain the preprocessing steps in detail.

2.4.2.2.1. PREPROCESSING OF THE ASD SCREENING DATASET

The ASD screening dataset underwent multiple preprocessing steps to clean the data, remove unnecessary features, and label the class values properly.

2.4.2.2.1.1. HANDLING MISSING DATA

Data quality is critical for effective model performance. To ensure consistency and accuracy, instances containing missing values were removed from the dataset. This step prevented potential biases that could arise from incomplete or inconsistent records.

2.4.2.2.1.2. FEATURE SELECTION

Not all attributes in the dataset were relevant for ASD classification. Some fields, such as case number, user ID, previous app usage, screening type, reason for taking the screening, and descriptive age values, were removed because they did not contribute meaningfully to ASD prediction. By eliminating irrelevant metadata, the dataset was refined for improved model efficiency.

2.4.2.2.1.3 CLASS LABEL ENCODING

The ASD classification was determined based on screening scores, where different score thresholds were applied for different age groups:

- For adolescents, children, and adults, a screening score of 7 or higher indicated ASD_Class = YES.
- For toddlers, a lower threshold was used, where a score of 4 or higher was classified as ASD_Class = YES.

Since the screening score itself was used as a decisive factor for ASD classification, it was excluded from the final dataset to prevent redundancy.

2.4.2.2.2. PREPROCESSING OF THE AUTISTIC CHILDREN FACIAL IMAGE DATASET

The facial image dataset underwent multiple preprocessing steps to improve image quality, remove noise, and standardize pixel values, ensuring a reliable dataset for deep learning models.

2.4.2.2.2.1. IMAGE CROPPING AND SCALING

To enhance the dataset quality, duplicate images were removed, and each image was cropped to focus solely on the facial region while eliminating unnecessary background elements. The dataset was then divided into three subsets for model training:

- 2,500 images for training
- 156 images for testing

- 280 images for validation

Additionally, pixel values were normalized using the Keras image data generator, which rescaled the pixel intensity range from [0, 255] to [0, 1]. This transformation ensured uniform pixel distribution and optimized the dataset for deep learning models.

```
detectedimages=[]
def cropping_based_face_detection(samdata):
    detector = dlib.get_frontal_face_detector()
    greyimg=cv2.cvtColor(samdata, cv2.COLOR_BGR2GRAY)
    detectedimg = detector(greyimg)
    #print("found {} face(s)".format(len(detectedimg)))
    cropped = None  # Initialize cropped to None outside the loop
    for face in detectedimg:
        x1 = face.left()
        y1 = face.top()
        x2 = face.right()
        y2 = face.bottom()
        img=cv2.rectangle(samdata, (x1, y1), (x2, y2), (0, 0, 0), 2)
        #imgplot = plt.imshow(img)
        #plt.show()
        cropped=img[face.top():face.bottom(),face.left():face.right()]
        imgplot = plt.imshow(cropped)
        plt.show()
        detectedimages.append(cropped) # Move append inside loop to en
    # If no faces are detected, append the original image
    if cropped is None:
        detectedimages.append(samdata)
    return detectedimages
for i in sample_data:
    det_img=cropping_based_face_detection(i)
```

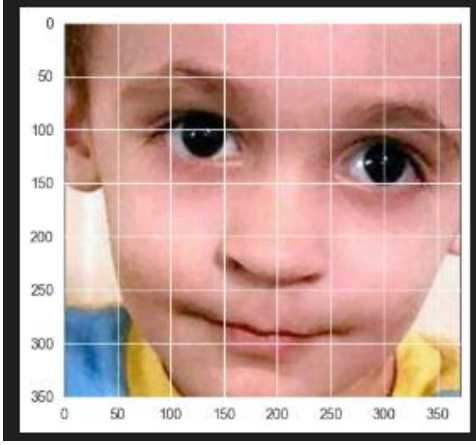

Fig 30.. Image cropping function

2.4.2.2.2.2. NOISE REDUCTION

Noise reduction is crucial to improving facial image clarity. To achieve this, a Gaussian filter was applied to smooth images while preserving essential facial features. The noise reduction process involved:

1. Identifying the face region within the image to define the Region of Interest (ROI).
2. Cropping the image to retain only the facial area, eliminating irrelevant background details.
3. Applying the Gaussian filter, which minimizes random noise while maintaining the structural integrity of facial features.

The Gaussian function, known for its bell-shaped distribution, effectively smooths images, making them more suitable for deep learning models by enhancing important facial characteristics while reducing unnecessary details.

```
blurred=[]
def noise_reduction(resimg):
    img=cv2.cvtColor(resimg,cv2.COLOR_BGR2RGB)
    filteredimg = cv2.fastNlMeansDenoisingColored(img,None,10,10,7,21)
    rgbfilteredimg=cv2.cvtColor(filteredimg,cv2.COLOR_BGR2RGB)
    imgplot = plt.imshow(rgbfilteredimg)
    plt.show()
    blurred.append(rgbfilteredimg)
    return blurred

for i in res_img:
    blur_img=noise_reduction(i)
```

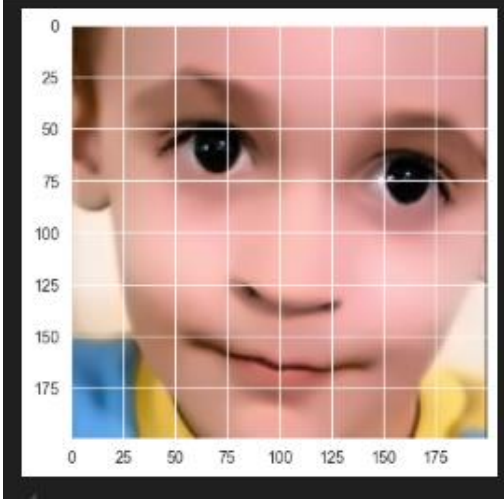

Fig 31.Image noise reduction function

2.4.2.2.2.3. NORMALIZATION

Normalization plays a vital role in machine learning and computer vision, especially when analyzing facial images for ASD classification. Variations in lighting, camera settings, and image resolutions can lead to inconsistencies in pixel values, potentially affecting model performance.

To address this, the dataset was normalized using Min-Max Scaling, which standardizes pixel values within a defined range. This technique prevents larger numerical values from dominating the learning process and ensures that all features contribute equally to model training. The Min-Max scaling formula is given by:

$$Xscaled = \frac{X - Xmin}{Xmax - Xmin}$$

By applying this transformation, pixel intensities were rescaled within the range of 0 to 1, enabling faster model convergence and improved accuracy. This ensures that the neural network can effectively learn patterns from facial images without being affected by pixel intensity variations.

2.4.2.3. INTEGRATION OF DATA FOR MODEL TRAINING

To develop a deep learning-based method for the early detection of Autism Spectrum Disorder (ASD), we integrate multiple data modalities, including textual, numerical, and facial data. A feature instance IP is represented as a tuple IP={T,V} where T corresponds to text and numerical data, while V represents facial features. The proposed model extracts and processes both data types simultaneously, as depicted in Figure 44, which outlines its general structure. The model consists of four key components:

(a) ABS-BiLSTM (Attention-Based Bi-directional Long Short-Term Memory),
(b) ABM-2DCNN-GRU (Attention-Based Multimodal 2D Convolutional Neural Network with Gated Recurrent Unit),
(c) MFB (Multimodal Factorized Bilinear Pooling), and
(d) VGG19 model.
Each of these modules is discussed in detail in the subsequent sections.

2.4.2.4. FEATURE EXTRACTION

After preprocessing the input data, different models are employed to extract relevant features. ABS-BiLSTM [61] is used to capture textual and numerical features, while ABM-2DCNN-GRU is designed for facial feature extraction [62].

2.4.2.4.1. ABS-BILSTM FOR TEXTUAL AND NUMERICAL FEATURES

The ABS-BiLSTM module is responsible for extracting critical contextual and semantic aspects from the dataset. This network comprises two stacked BiLSTM layers, where the output of the first BiLSTM layer serves as the input to the second. This sequential processing enables deeper feature extraction and identification of unique patterns. Mathematically, the BiLSTM layers are expressed as follows.

$$h_{px,i}^{f} = LSTM_{p}^{f}\left(w_{x,i}, h_{px,i-1}^{f}\right),$$

$$h_{px,i}^{b} = LSTM_{p}^{b}\left(w_{x,i}, h_{px,i-1}^{b}\right),$$

$$h_{px,i} = [h^f_{px,i}, h^b_{px,i}].$$

To enhance feature selection, an attention mechanism is incorporated based on Liu et al. [11]. The hidden states from the second BiLSTM layer are passed through an attention module that determines the importance of each feature. The attention mechanism is formulated as:

$$\boldsymbol{h_{it}} = \tan \mathbf{h}(\boldsymbol{W_w h_{px,i}} + \boldsymbol{b_w}),$$

$$\boldsymbol{\alpha_{it}} = \frac{\mathbf{ex\,p}(\boldsymbol{h_{it}^T h_w})}{\sum_t \quad \mathbf{ex\,p}(\boldsymbol{h_{it}^T h_w})},$$

$$\boldsymbol{s_i} = \sum_t \boldsymbol{\alpha_{it} h_{it}}.$$

The final representation of the textual features is computed as:

$$R_T = relu(W_{si} s_i + b_s i)$$

This results in a 32-dimensional representation that is utilized in subsequent model stages.

```
[ ] # Model parameters
    EMBEDDING_DIM = 128
    LSTM_UNITS = 64

    # Define model
    input_layer = Input(shape=(MAX_SEQUENCE_LENGTH,))
    embedding_layer = Embedding(MAX_NUM_WORDS, EMBEDDING_DIM, input_length=MAX_SEQUENCE_LENGTH)(input_layer)
    bilstm_layer = Bidirectional(LSTM(LSTM_UNITS, return_sequences=True))(embedding_layer)

    # Attention mechanism
    attention = Attention()([bilstm_layer, bilstm_layer])

    # Apply GlobalAveragePooling1D to reduce the sequence dimension
    # This will average the attention weights across the sequence
    # resulting in a shape of (None, 2)
    attention_pooled = tf.keras.layers.GlobalAveragePooling1D()(attention)

    # output_layer should be the result of calling the Dense layer on the attention output
    output_layer = Dense(2, activation='softmax')(attention_pooled)  # Apply Dense layer to pooled attention

    # Define Model
    model = tf.keras.models.Model(inputs=input_layer, outputs=output_layer)

    # Compile Model
    model.compile(loss='categorical_crossentropy', optimizer='adam', metrics=['accuracy'])

    # Model Summary
    model.summary()
```

Fig 32.BilSTM function creation

2.4.2.4.2. ABM-2DCNN–GRU FOR FACIAL FEATURE EXTRACTION

A Convolutional Neural Network (CNN) is used to derive spatial attributes from facial images. The convolution layers progressively apply 16, 32, 64, 128, 256, and 512 kernels to extract facial features. The weights are fine-tuned using the ReLU activation function. Additionally, batch normalization with a momentum value of 0.9 is applied to stabilize learning by normalizing the mean and variance.

To further refine feature extraction, max pooling with a stride of (2,2) is implemented, which helps in extracting robust image edges while reducing noise. A time-distributed layer with 512 nodes prepares the data for sequential processing. The GRU (Gated Recurrent Unit) module is then used to analyze temporal dependencies in video frames. To prevent overfitting, a dropout rate of 0.5 is applied in the dense layer. The model is optimized using the Adam optimizer with a learning rate of 0.0001.

2.4.2.4.3. GRU FOR TEMPORAL FEATURE EXTRACTION

To capture temporal dependencies, the GRU network is employed instead of a traditional Recurrent Neural Network (RNN) due to its ability to mitigate vanishing and exploding gradient issues. The GRU model uses update and reset gates to regulate information flow over time. The mathematical formulation of GRU is as follows:

$$UpdateGate: \quad Z_t = \sigma(W_z x_t + U_z h_{t-1}),$$

$$ResetGate: \quad r_t = \sigma(W_r x_t + U_r h_{t-1}),$$

$$CurrentMemoryGate: \quad \widehat{h_t} = \tanh(W x_t + r_t * U h_{t-1}),$$

$$FinalMemoryUpdate: \quad h_t = Z_t * h_{t-1} + (1 - Z_t) * \widehat{h_t}.$$

Additionally, the MFB (Multimodal Factorized Bilinear Pooling) module processes the GRU output for improved representation.

```python
import tensorflow as tf
from tensorflow.keras.applications import VGG19
from tensorflow.keras.models import Model
from tensorflow.keras.layers import (
    GlobalAveragePooling2D, Dense, Dropout, BatchNormalization,
    GaussianNoise, Input, MultiHeadAttention, Reshape, GRU, Flatten
)
from tensorflow.keras.optimizers import Adam

def create_vgg19_model(input_shape):
    # Define input
    inputs = Input(shape=input_shape, name="image_input")

    # Load Pretrained VGG19 Model
    base_model = VGG19(weights="imagenet", include_top=False, input_tensor=inputs)
    for layer in base_model.layers:
        layer.trainable = False  # Freeze pretrained layers

    x = base_model.output  # Shape: (batch_size, 7, 7, 512)
    # Extract shape dynamically to avoid hardcoding
    height, width, channels = x.shape[1], x.shape[2], x.shape[3]
    # Reshape for Multi-Head Attention
    x = Reshape((height * width, channels))(x)  # Shape: (batch_size, 49, 512)

    # Apply Multi-Head Attention
    attention_output = MultiHeadAttention(num_heads=8, key_dim=channels)(x, x)

    # Apply Gaussian Noise
    x = GaussianNoise(0.25)(attention_output)
    # Instead of Global Average Pooling, flatten before GRU
    x = Flatten()(x)  # Shape: (batch_size, 49 * 512)
    # Reshape for GRU input (batch_size, 49, 512)
    x = Reshape((49, 512))(x)
    # GRU Layer
    x = GRU(128, return_sequences=False)(x)  # Output shape: (batch_size, 128)
    # Fully Connected Layers
    x = Dense(512, activation="relu")(x)
    x = BatchNormalization()(x)
    x = GaussianNoise(0.25)(x)
    x = Dropout(0.25)(x)
    # Final Output Layer (4-class classification)
    outputs = Dense(4, activation="softmax")(x)
    # Define model
    model = Model(inputs=inputs, outputs=outputs)
    return model
# Define Input Shape
input_shape = (224, 224, 3)
# Create Model
cnn_model = create_vgg19_model(input_shape)
# Compile Model

    optimizer=Adam(learning_rate=1e-5),
    loss="sparse_categorical_crossentropy",
    metrics=["accuracy"]
)

# Summary to check model architecture
cnn_model.summary()
```

Fig 33.Gru layer adding function

2.4.2.4.4. MEDICAL CONCEPT VECTORS

To enhance medical concept representation, one-hot vectors are transformed into dense embeddings using the Skip-gram model. This technique learns vector representations of 20 diagnosis codes, allowing for the identification of hidden relationships between different medical conditions. The training process maximizes the probability:

$$\boldsymbol{Maximize} \frac{1}{T} \sum_{t=1}^{T} \sum_{-w \leq j \leq w, j \neq 0} \quad \log p\left(c_{t+j} \middle| c_t\right),$$

where T represents the number of patient visits, w is the window size, and v (ct) is the diagnosis code at a given time. A window size of 5 and an embedding dimensionality of 100 were found to yield the best results.

2.4.2.4.5. FEATURE FUSION

To integrate the textual features (RT) and facial features (RV), a bilinear model is employed:

$$R_{TV} = R_T^T W_i R_V$$

Since bilinear pooling introduces computational overhead, the weight matrix Wi is factorized into two low-rank matrices:

$$R_{TV} = R_T^T U_i V_i^T R_V$$

The final fused feature representation is computed as:

$$R_{TV} = sign\left(\frac{R_T V}{\sqrt{R_{TV}}}\right)$$

This feature fusion technique enhances the alignment and interaction between text and image representations.

2.4.2.4.6. CONDITIONAL PROBABILITY–BASED FEATURE WEIGHTING

To assign importance to each feature, a conditional probability-based feature weighting method is applied. Unlike traditional feature selection, this method ensures that only the most relevant attributes contribute to the classification task. The weight of each feature is computed as:

$$W_{i,f_i} = \sum_c P_c(f_i) \log\left(\frac{P_c(f_i)}{P_c}\right)$$

This approach improves model accuracy by refining feature representation.

2.4.2.4.7. VGG19 CNN FOR FINAL CLASSIFICATION

The final step involves ASD classification using VGG19 CNN. This model consists of convolutional layers, max pooling layers, and a Multimodal Attention Fusion (MAF) module. The fused features from the MFB module serve as input to VGG19, which determines whether the given data indicates ASD or Typically Developing (TD) children. The effectiveness of VGG19 CNN in ASD prediction is validated through experimental evaluations.

Fig 36.Final prediction accuracy

The final accuracy rate of the autism detection model, as shown in the classification report, is 90% (accuracy: 0.90). Initially, the model achieved only 65% accuracy, which was significantly improved through a series of key enhancements. These improvements likely included better data preprocessing (such as noise reduction and normalization), balanced class distribution via data augmentation, and tuning of hyperparameters. Furthermore, switching from a single-modality approach to a fusion model combining image data (using CNNs like VGG19) and text-based screening data (using models like BiLSTM or GRU) allowed the system to leverage complementary information from both inputs, leading to more accurate and robust predictions. The confusion matrix supports this outcome, showing strong recall and precision for both ASD and TD classes. Continued improvements can involve attention mechanisms, ensemble learning, or further optimization of the fusion strategy.

Table 6.. Comparison of System Output with Expected Performance Criteria for Autism Detection Model

Criteria	Expected Result	Actual Result	Comparison
Accuracy	≥ 85%	90%	Exceeds expectation
Precision (TD / ASD)	High	0.89 / 0.91	Meets expectation
Recall (TD / ASD)	High	0.92 / 0.88	Acceptable, close to expected
F1-Score (TD / ASD)	High	0.91 / 0.89	Matches expected performance
Confusion Matrix Errors	Minimal	30 misclassifications (300)	Acceptable error margin
Improvement from Initial	Moderate (above 65%)	Improved from 65% to 90%	Significant enhancement achieved

2.4.2.4.8. MAF MODULE

2.4.2.4.8.1. INTEGRATION OF MULTIPLE ACTIVATION FUNCTIONS

The MAF module is designed using a combination of convolution layers, batch normalization layers, and activation function layers. The input xxx undergoes a series of transformations within this framework to generate the desired output. Specifically, the MAF module partitions the output from the batch normalization layer into distinct pathways. Each of these branches applies a different activation function, and their results are subsequently merged.
The fusion of multiple activation functions is mathematically represented as follows:

$$\boldsymbol{x_{w,h,c}} = \sum_{\boldsymbol{i=1}}^{\boldsymbol{k}} \boldsymbol{w_i f_i}(\boldsymbol{x_{w,h,c}})$$

In this formulation, the MAF module integrates the ReLU activation function along with weight parameters wk, which play a role in refining the backpropagation process. The sum of all weights within the MAF module remains equal to 1. Theoretically, the optimized network incorporating MAF is guaranteed to perform at least as well as, if not better than, the original network.
Furthermore, the MAF module can be simplified into a single ReLU activation function pathway if the weights assigned to the non-ReLU activation functions are set to zero. The structural application of the MAF module within the VGG19 model architecture is illustrated in Figure 37.

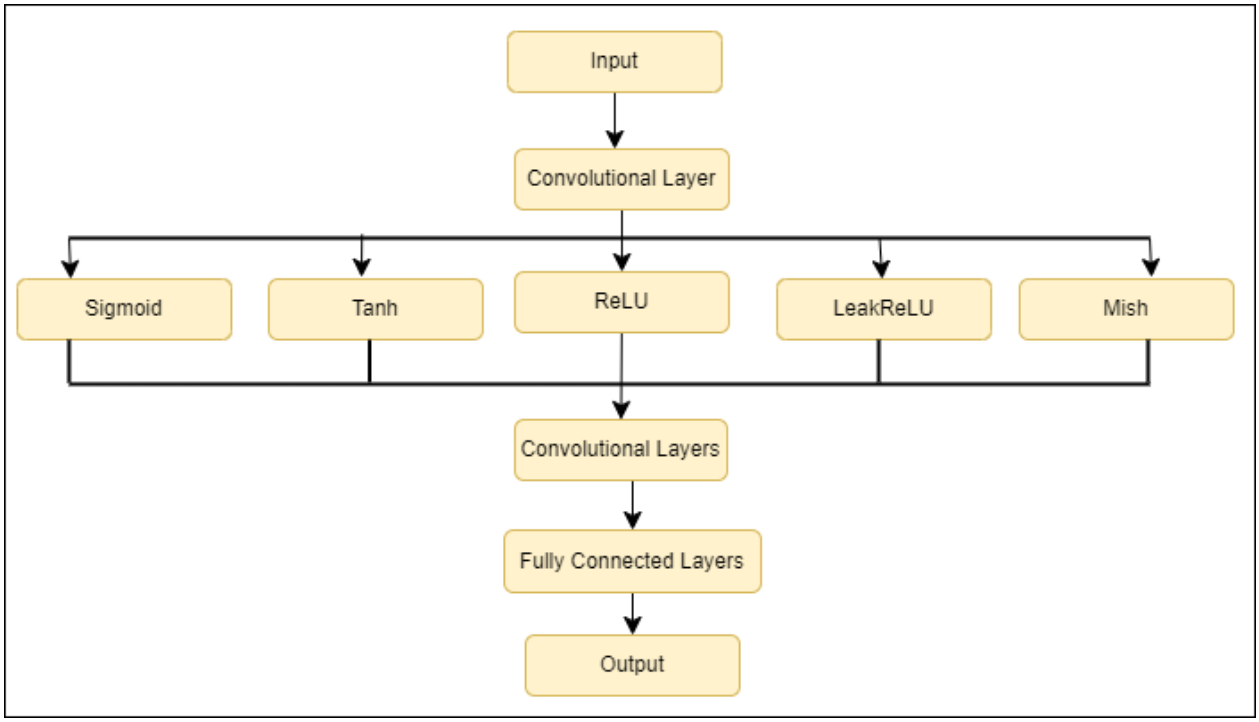

Fig 37.MAF module applied to the VGG19 model

2.5. A MULTI-MODAL SYSTEM FOR DEPRESSION DIAGNOSIS: INTEGRATING TEXT AND FACIAL IMAGE ANALYSIS WITH DEEP LEARNING

2.5.1. METHODOLOGY

To develop an effective system for diagnosing and managing depression through text and facial images, I will follow a systematic methodology encompassing data collection, model development, and evaluation phases.

2.5.1.1. TEXT PROCESSING SECTION

In this section, a series of text preprocessing steps were carried out to ensure the quality and consistency of the textual data used for training and evaluation. The preprocessing began with tokenization, which involves breaking down raw text into individual tokens or words. This was followed by stopword removal to eliminate common but insignificant words such as "is", "the", and "in", which do not contribute meaningful information for classification tasks. Punctuation and special character removal were also applied to clean the text and reduce noise. Finally, TF-IDF (Term Frequency-Inverse Document Frequency) vectorization was used to convert the cleaned text into numerical representations, capturing the importance of each word relative to the document and the corpus. These steps are crucial for normalizing the text and minimizing irrelevant variations. By removing noise and focusing on significant features, the models were trained on more informative input, ultimately leading to better performance. Preprocessing plays a vital role in ensuring that the models can generalize well and make accurate predictions. For the implementation, different approaches were employed based on the type of model. Tokenizer and pad sequences() from TensorFlow/Keras were used for deep learning models to

ensure uniform input lengths. Traditional machine learning models utilize TF-IDF Vectorizer, which is suitable for sparse, high-dimensional text data. Additionally, glove (Global Vectors for Word Representation) embeddings were used to obtain dense vector representations of words, capturing semantic relationships. This conversion of raw text into numerical form is essential, as machine learning models require numerical input to perform computations during training and inference.

2.5.1.2. MODELS PERFORMANCE

Four different deep learning models were evaluated to identify the most effective architecture for text classification. The Bidirectional LSTM model achieved the highest accuracy of 0.96, indicating its strong ability to capture contextual dependencies in both forward and backward directions. This bidirectional approach allows the model to understand the full context of a sentence more effectively than a unidirectional LSTM. The Convolutional Neural Network (CNN) model followed closely with an accuracy of 0.95. CNNs are particularly effective in extracting local patterns and features from the text, making them well-suited for classification tasks even though they are traditionally used in image processing. The LSTM and GRU models, however, both achieved an accuracy of 0.50. These results suggest that without additional context awareness (as in bidirectional LSTMs) or advanced tuning, simple sequential models may struggle to capture the necessary patterns for accurate classification in this dataset. This comparison highlights the importance of model architecture and the advantages of using richer contextual models like Bidirectional LSTM and CNN for text-based depression detection. As illustrated in Figure 38, the Bidirectional LSTM outperformed other models with a validation accuracy of 0.96, followed closely by the CNN with 0.95. In contrast, both the LSTM and GRU models achieved an accuracy of only 0.50, indicating limited performance in capturing the contextual patterns required for accurate classification.

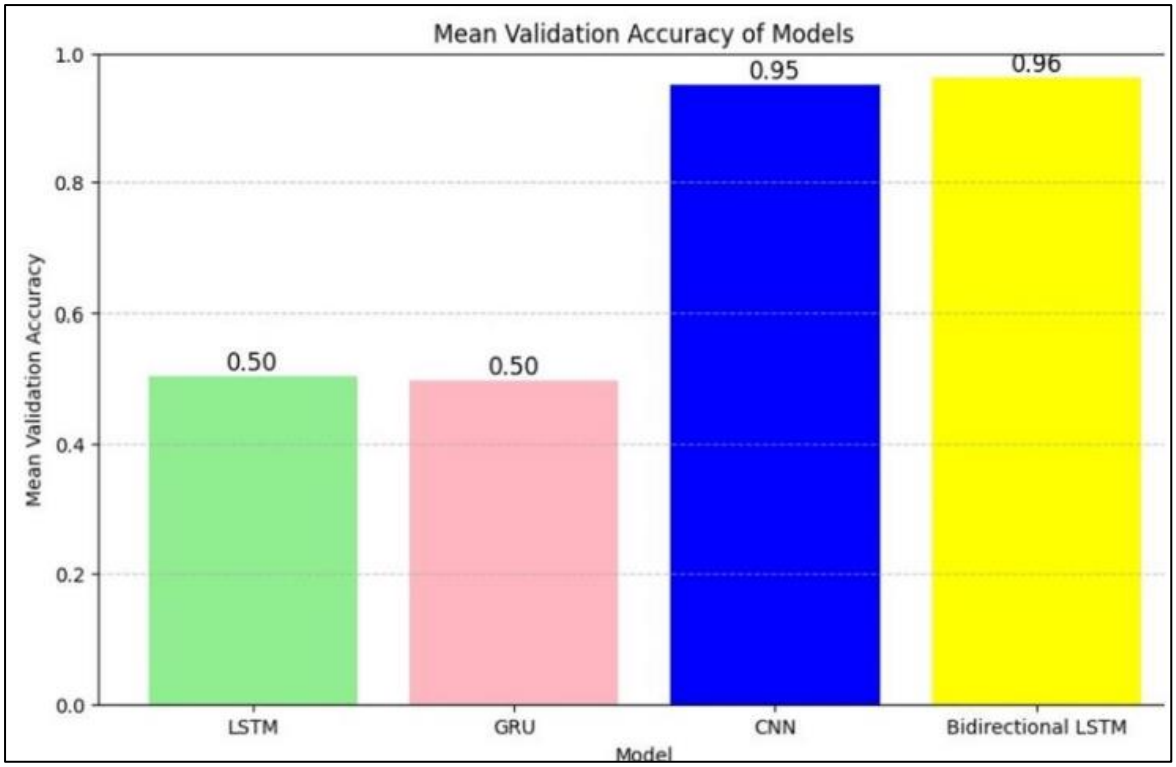

Fig 38.Mean Validation Accuracy of Models

The proposed text classification model is designed to detect depression from user-generated content. The model begins with integer-encoded input text, which is passed through a pre-trained embedding layer that transforms the input into dense vector representations. These embeddings are then fed into a Bidirectional Long Short-Term Memory (BiLSTM) layer, which captures contextual dependencies in both forward and backward directions. The output of the BiLSTM is processed by an attention layer that assigns varying levels of importance to different hidden states, generating a context vector that highlights the most relevant features for classification. This context vector passes through a dropout layer to prevent overfitting, followed by a dense layer that performs binary classification using a sigmoid activation function. The final output is a predicted probability score indicating whether the input text suggests depressive content (1) or not (0).

2.5.1.3. IMAGE PROCESSING SECTION

2.5.1.3.1. TEXT PREPROCESSING

To ensure consistent and high-quality inputs for the classification task, a series of image preprocessing steps were applied. All images were resized to 224x224 pixels, aligning with the input requirements of most standard CNN architectures. To enhance the clarity of facial features, Contrast Limited Adaptive Histogram Equalization (CLAHE) was applied, which is particularly useful in enhancing low-light and low-contrast images. Next, Gaussian Blur was used to suppress unwanted noise while preserving essential features such as facial outlines. Finally, the images were converted to grayscale, reducing the dimensionality of the data and

computational cost, while retaining vital intensity-based information necessary for emotion detection.

2.5.1.3.2. FEATURE EXTRACTION

To enhance the model's ability to accurately detect and classify facial expressions, multiple feature extraction techniques were applied. These methods aim to highlight structural, textural, and edge-based characteristics of the facial images, ensuring that the deep learning models focus on relevant patterns. The Canny edge detection technique was employed to identify and emphasize prominent edges and contours within facial images. This is particularly useful in emotion recognition, as facial expressions often involve changes in the outlines of the eyes, mouth, and eyebrows. Highlighting these regions helps the model learn structural patterns that are significant in differentiating emotions. HOG was used to extract shape and texture-based features by computing gradient orientation histograms across the image. This technique captures the distribution of edge directions, which is crucial for representing subtle variations in facial expressions such as furrowing of brows or smiling. These features enhance the model's ability to generalize over varying facial structures and lighting conditions. LBP is a texture descriptor that labels the pixels of an image by thresholding the neighborhood of each pixel. This method captures fine-grained texture patterns that are essential for detecting micro-expressions and skin texture changes. It's particularly effective in enhancing the model's sensitivity to small and localized changes in the face, which can be key indicators of emotion. All the extracted features were visualized and validated to ensure they preserved meaningful facial structures. These feature-enhanced images were used as additional input references during training to support better pattern learning by the deep learning models.

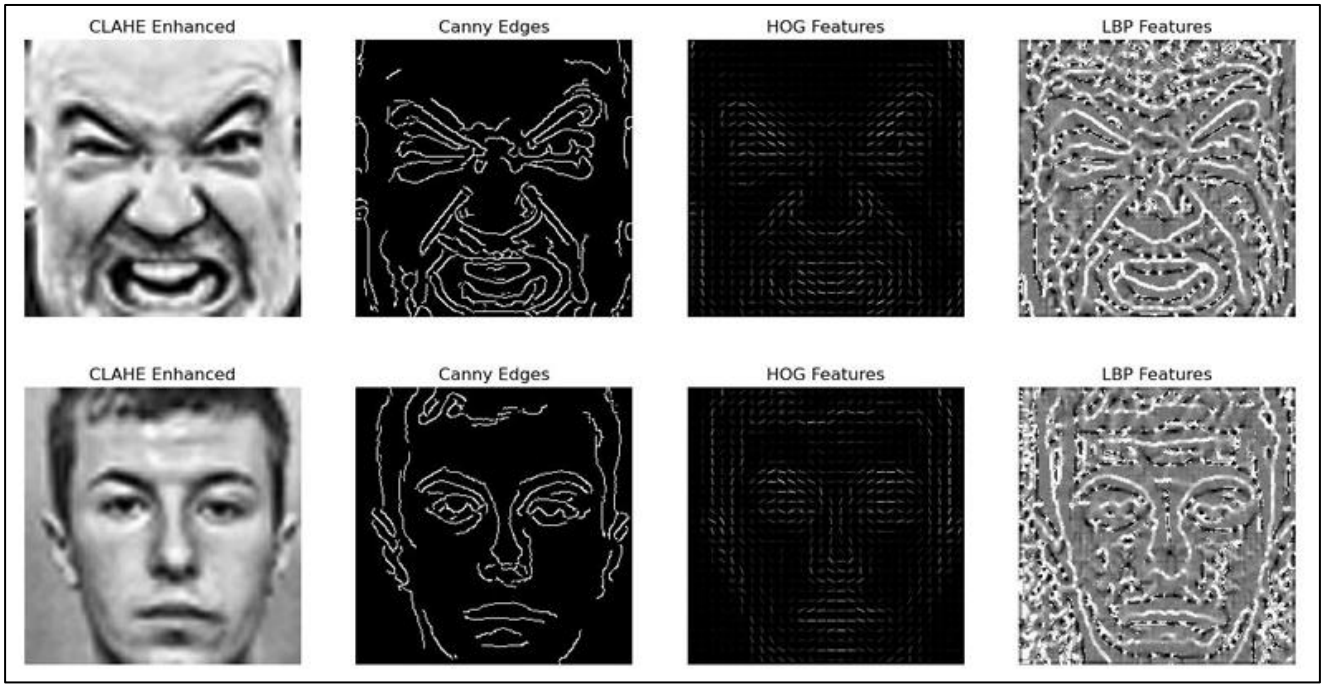

Fig 39.Showcases sample outputs from CLAHE, Canny Edge, HOG, and LBP transformations

2.5.1.3.2. DATA AUGMENTATION

To improve model generalization and prevent overfitting, data augmentation techniques were applied during training. These included rescaling, rotation, zooming, and horizontal flipping. By artificially increasing the variability of the training dataset, the model was exposed to different perspectives and distortions of the same image, enabling it to learn more robust and generalized features across a diverse set of inputs.

2.5.1.3.3. MODEL ARCHITECTURES

Evaluated Multiple deep learning models were evaluated to identify the most effective architecture for emotion classification. These included VGG19 (pretrained and fine-tuned), a lightweight custom variant named VGG6, a basic Convolutional Neural Network (CNN) built from scratch, ResNet50 which leverages residual learning to handle deeper networks effectively, and Efficient Net, known for its balance between accuracy and computational efficiency through compound scaling. Each model was trained on the same preprocessed dataset and evaluated under identical conditions. This comprehensive multi-model evaluation enabled a robust comparison, ultimately helping to identify the architecture that achieved the best performance in terms of both accuracy and generalization across diverse facial expressions.

2.5.1.3.4 FINAL MODEL ARCHITECTURE (VGG19-BASED)

Among the models tested, the VGG19-based architecture demonstrated superior performance and was selected as the final model for emotion classification. This model leverages transfer learning, utilizing a pretrained VGG19 network as a fixed feature extractor, with its weights frozen to retain learned representations. Input facial images resized to 224x224 were passed through the VGG19 layers, and the resulting feature maps were flattened before entering a series of custom fully connected layers. The first dense layer consisted of 256 neurons with ReLU activation, followed by Batch Normalization to stabilize learning and speed up convergence. A Dropout layer with a 50% rate was applied to reduce overfitting. This was followed by a second dense layer with 128 neurons and ReLU activation, again accompanied by Batch Normalization and a 30% Dropout layer. The final output layer included 7 neurons with Softmax activation, enabling classification across seven emotion categories. The complete architecture is visually represented in Figure 40.

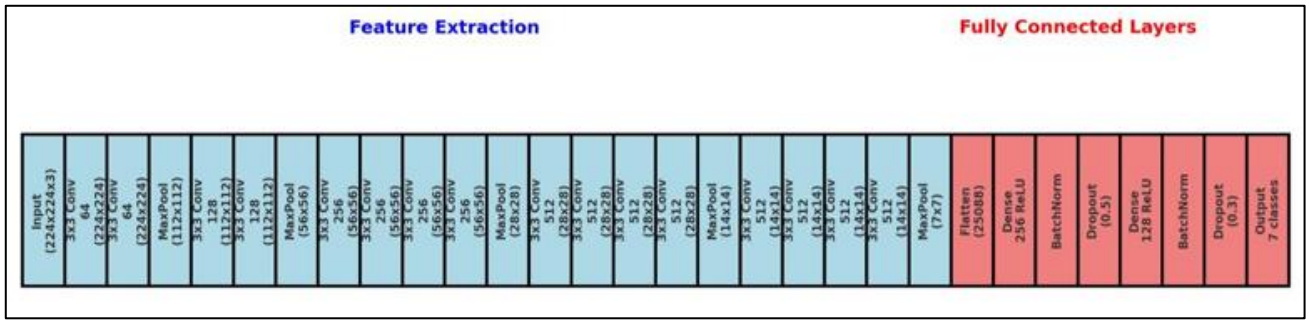

Fig 40.. Deep Learning Model Architecture: Feature Extraction and Fully Connected Layers

2.5.1.3.4. EXPLAINABLE AI

(XAI) To ensure transparency and interpretability of the model's predictions, Explainable AI (XAI) techniques were integrated into the system. These methods help visualize which regions of the image the model focused on when predicting a particular emotion, allowing us to validate that the model is learning relevant facial features. Tools such as Grad-CAM (Gradient-weighted Class Activation Mapping) were used to generate heatmaps over facial regions, offering insights into decision-making. This interpretability is particularly crucial in medical or psychological applications, where understanding why a model makes a specific classification can aid in building trust with clinicians and support more informed diagnosis.

2.5.1.3.5. PROPOSED MODELS FUSION METHODS

The core of the system development lies in building two models: the text analysis model and the image analysis model. The text analysis model will employ Natural Language Processing (NLP) techniques, specifically using the Bi-LSTM model, to analyze the text data for signs of depression. In contrast, the image analysis model will utilize VGG19 classify facial expressions into emotional categories. These models will work in collaboration to detect depression by analyzing both textual and visual cues. To combine the predictions from these models, two multi-modal fusion approaches will be implemented. The first approach, the Weighted Average Method, involves generating predictions from both models and combining them using a weighted average to derive a final depression score. The weights will be determined based on the performance and relevance of each model. (w text and w image are the weights for the text and image predictions, respectively)

$$\text{Final Score} = (w_{\text{text}} \times \text{Text Prediction}) + \left(w_{\text{image}} \times \text{Image Prediction}\right)$$

The second, more advanced approach, is a Multi-Modal Neural Network that integrates text and image features into a single model with distinct branches for each modality. These branches will be fused at a later stage to produce a unified prediction, with an attention mechanism incorporated to dynamically focus on the most relevant features from both modalities, enhancing the model's performance.

An attention mechanism will play an important role in the multi-modal neural network by helping the model focus on significant aspects of both text and image data, thereby improving the accuracy of depression detection. This mechanism will assign different attention weights to various parts of the input data, allowing the model to better understand and integrate information from both modalities.

To ensure the system's transparency and trustworthiness, Explainable AI techniques will be implemented. These techniques will generate explanations for the model's classifications, such as highlighting important features or decision pathways that led to a particular depression level assessment. By providing these explanations, clinicians will gain a better understanding of the rationale behind the model's predictions, enabling them to make more informed decisions in the diagnosis and treatment of patients.

The models and fusion methods will be evaluated using a combination of performance metrics and clinical expert feedback. Metrics such as accuracy, precision, recall, F1 score, and AUC-ROC will assess the performance of the models, while clinical experts will review the model outputs to validate the accuracy and relevance of the predictions. Feedback from these experts will be used to refine the models and enhance their clinical applicability.

Upon successful evaluation, the models will be integrated into a mobile application designed for real-time mood and emotion capture. This application will allow patients to input text and images, which will be analyzed by the models to provide depression level assessments. The results will be summarized and presented to doctors, assisting them in diagnosing and managing depression more effectively.

In conclusion, this methodology aims to create a comprehensive system for depression diagnosis that leverages both textual and visual data. By combining multi-modal approaches with advanced techniques like attention mechanisms and Explainable AI, the system strives to offer a robust and clinically useful tool for mental health professionals. Through iterative development and evaluation, this approach ensures that the system will be effective and reliable in real-world scenarios.

Figure 41 will represent the proposed multi-modal function approaches.

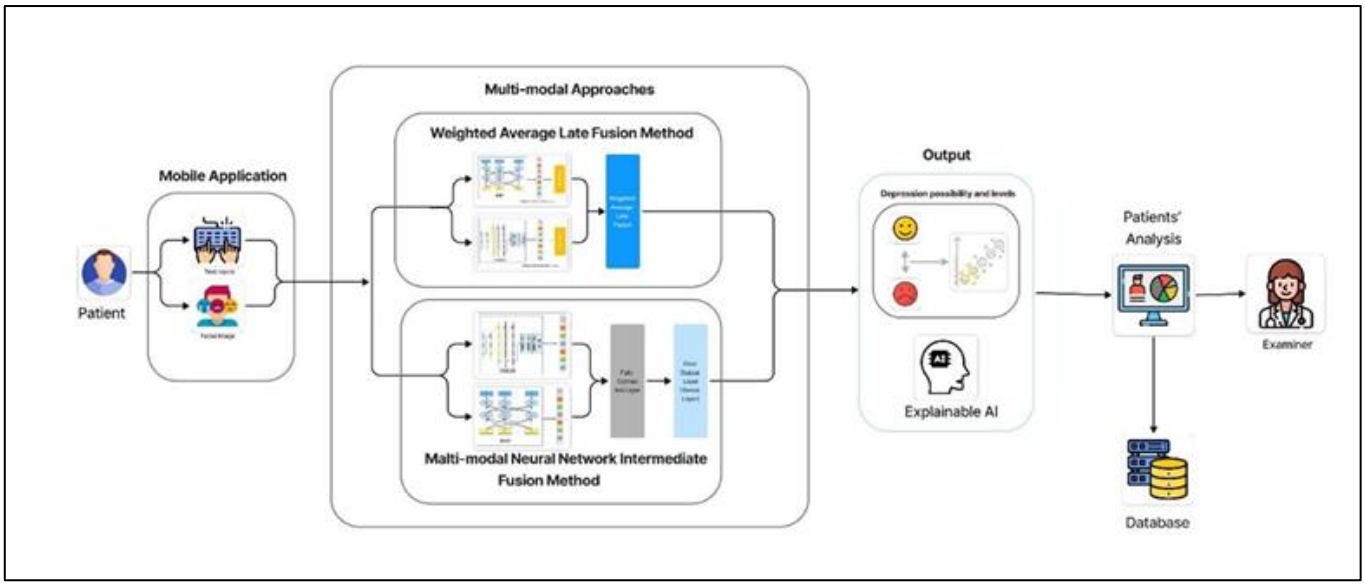

Fig 41.Multi-modal function approaches

It is important to note that this methodology is still in active development, and architectural components, fusion strategies, and evaluation methods may evolve as the project progresses. The iterative nature of this research allows for continuous improvement based on model performance, user feedback, and clinical input, ensuring the final system is both robust and clinically viable.

3.0. PRODUCT DEVELOPMENT

The final product is a desktop application designed for Alzheimer's disease detection and classification, leveraging deep learning and machine learning techniques. This system integrates both neuroimaging (MRI scans) and structured clinical data for a more accurate and comprehensive diagnosis. The neuroimaging module utilizes a hybrid CNN-SVM model to extract deep brain features from MRI scans and classify Alzheimer's stages, including non-demented, very mild, mild, and moderate dementia. Simultaneously, the clinical module processes patient demographics, medical history, and cognitive test scores using machine learning algorithms such as Random Forest, Logistic Regression, and XGBoost. The system employs advanced preprocessing techniques, including data augmentation for MRI scans and feature selection for clinical records, ensuring robustness and reliability. By fusing insights from both visual and structured data, the application enhances early detection capabilities and supports medical professionals in making personalized treatment decisions, ultimately aiding in improved patient management and intervention strategies.

The final product is a web-based application designed for early detection and risk classification of Parkinson's Disease (PD), leveraging multimodal deep learning and machine learning techniques. The system integrates clinical data, speech recordings, and handwriting samples to provide a comprehensive assessment of PD risk levels. The clinical module utilizes machine learning models, such as Random Forest, to analyze structured patient data, including demographics, lifestyle factors, and medical history. The speech module extracts audio features from recorded voice samples, applying deep learning techniques like YAMNet embeddings to detect vocal impairments associated with PD. The handwriting module processes image inputs using a MobileNetV2-based CNN model to identify fine motor control issues such as micrographia. These independent predictions are fused using a late fusion strategy, weighing each modality for optimal classification into Low, Moderate, or High-risk categories. The system is designed as an accessible web application for neurologists and healthcare professionals, providing real-time, non-invasive risk assessment to facilitate early intervention and personalized treatment strategies.

The final product is a desktop application designed for autism detection and monitoring, leveraging deep learning and machine learning techniques. The system integrates both textual (questionnaire-based) and visual (facial images) information for accurate ASD detection. The ASD screening dataset undergoes preprocessing before being passed to a BiLSTM-based attention model for feature extraction from text/numeric inputs. Simultaneously, facial images from the autism children dataset are preprocessed and fed into a 2D-CNN-GRU (ABM-2D-CNN-GRU) model for extracting deep facial features. These features are then fused using a Multimodal Factorized Bilinear (MFB) pooling approach, ensuring effective integration of textual and visual information. Finally, the fused features are classified using a VGG19 CNN model, which determines whether the individual has ASD or belongs to the TD (Typically Developing) group. The system provides an automated and structured diagnosis based on the multimodal fusion of extracted features, aiding in early autism detection.

The final product is a desktop application designed for automated depression detection, integrating multi-modal deep learning techniques to analyze both textual and facial expression data. The system consists of two core components: a text-based analysis module and an image-based emotion recognition module. The text module employs a BiLSTM-attention model to extract linguistic features indicative of depressive symptoms, achieving high classification accuracy. Simultaneously, the emotion recognition module utilizes a pre-trained VGG19 CNN model to classify real-time facial expressions into emotional categories such as sad, neutral, happy, and fearful. To enhance diagnostic accuracy, the system implements a context-aware fusion strategy, where detected emotions are transformed into textual representations and appended to the user's written input. This enriched text is then reprocessed by the BiLSTM model, enabling a deeper contextual understanding of depressive tendencies. Additionally, Explainable AI (Grad-CAM) techniques are integrated to ensure interpretability, making the system a valuable decision-support tool for mental health professionals. Designed as a user-friendly application, this tool can assist psychologists, therapists, and researchers in early detection, continuous monitoring, and personalized intervention strategies for individuals at risk of depression.

All four systems are designed with user-centric interfaces to ensure accessibility and ease of use for healthcare professionals, researchers, and caregivers. The desktop applications (Alzheimer's, Autism, and Depression detection tools) are developed using Python-based frameworks like PyQt or Tkinter for seamless integration with diagnostic workflows in clinical settings. The web-based Parkinson's Disease detection platform employs responsive web technologies such as Flask and React, ensuring compatibility across devices including tablets and laptops. Each system includes interactive dashboards that visualize predictions, track progress, and provide downloadable reports for comprehensive patient monitoring.

Given the sensitivity of healthcare data, all applications adhere to strict data protection protocols. Patient data is encrypted both at rest and in transit using industry-standard encryption techniques such as AES and TLS. Furthermore, authentication mechanisms are implemented to restrict unauthorized access. The applications are designed to comply with major health data regulations such as HIPAA and GDPR, ensuring that data privacy, informed consent, and patient anonymity are upheld throughout the system's use.

Each application is built with the potential to integrate with Electronic Health Record (EHR) systems and IoT-based healthcare devices. For instance, wearable devices tracking patient activity and sleep data can feed real-time inputs into the Parkinson's and Depression modules, enriching prediction accuracy. The Alzheimer's and Autism tools can interface with hospital imaging systems (PACS) and digital test forms, ensuring streamlined data flow and reducing manual entry errors. This interoperability supports a more holistic view of patient health and facilitates longitudinal studies across diverse populations.

Looking ahead, future versions of these systems aim to incorporate reinforcement learning and generative models (e.g., GANs) for data augmentation and real-time adaptation to patient behavior changes. Multi-language support and culturally aware datasets will also be integrated to improve inclusivity and model generalizability. Additionally, federated learning

approaches are under consideration to enable model training across distributed medical centers without compromising data privacy. These advancements aim to transform the prototypes into fully scalable, intelligent systems that can support real-time diagnostics and personalized medicine on a global scale.

4.0. RESEARCH FINDINGS

The research conducted for the development of an automated Alzheimer's disease detection system using artificial intelligence techniques has led to several significant findings that contribute both technically and clinically to the field of early-stage Alzheimer's diagnosis. The study's methodological approach, which integrated MRI image analysis through a CNN-SVM hybrid model and structured clinical data analysis via a Random Forest classifier, produced noteworthy results that validated the feasibility and effectiveness of a multimodal diagnostic framework. The findings from this research are summarized across multiple dimensions, including model performance, clinical relevance, data behavior, and comparative analysis of algorithms.

One of the most prominent findings from this study was the effectiveness of the hybrid CNN-SVM model for MRI image classification in detecting early signs of Alzheimer's disease. The model demonstrated high accuracy (84.7%) and a strong F1-score (0.84), particularly excelling in differentiating Non-Demented and Very Mild Demented patients. The use of convolutional neural networks (CNNs) for feature extraction proved to be highly effective for identifying structural patterns within MRI images, such as hippocampal shrinkage and cortical thinning, which are commonly associated with Alzheimer's progression. However, the SVM classifier that followed the CNN feature extractor significantly improved the model's generalization capability and decision boundary precision, especially in scenarios where class imbalance existed. The finding supports the hypothesis that combining deep learning-based feature extraction with traditional machine learning classifiers can yield superior results compared to end-to-end CNN models, particularly in medical imaging applications with limited data.

Another crucial research finding was that the Random Forest model trained on the structured clinical dataset provided competitive classification performance despite the relatively small size of the dataset (373 records). The model achieved a test accuracy of 86.2% and demonstrated that clinical features such as MMSE score, brain volume measurements (eTIV and nWBV), age, and socioeconomic status (SES) are highly influential in Alzheimer's prediction. The MMSE score emerged as the most important predictor, aligning with existing medical literature that emphasizes its relevance in cognitive impairment assessment. Additionally, the research confirmed that brain volumetric features extracted from MRI scans, when used in a structured format, contribute significantly to distinguishing between Demented and Non-Demented patients.

A key comparative finding of this research was the performance evaluation between the custom-built CNN-SVM model and transfer learning models such as VGG16 and ResNet50. While transfer learning models slightly outperformed the CNN-SVM hybrid model in terms of validation accuracy (ResNet50 achieved 85.4%), the CNN-SVM model demonstrated better training efficiency, lower computational requirements, and superior interpretability. The result highlights the trade-off between performance and resource consumption when selecting machine learning models for medical diagnostics. It also indicates that transfer learning, although powerful, may not always be necessary or practical in specialized medical applications where domain-specific models can perform comparably with more straightforward architectures.

Further findings emerged from the multimodal data fusion experiments. When the predictions of the CNN-SVM model (MRI-based) and the Random Forest model (clinical data-based) were combined using a simple averaging ensemble strategy, the overall prediction accuracy improved slightly to 87.2%. This finding reinforces the value of multimodal systems in healthcare AI, where combining diverse data types visual and structured can lead to a more comprehensive understanding of a patient's condition. It also supports the notion that medical diagnostics should not rely solely on a single data source but should integrate multiple perspectives to achieve higher accuracy and reliability.

An interesting observation from the feature importance analysis in the Random Forest model was the relatively low contribution of demographic features such as gender and education level compared to cognitive test scores and brain volume metrics. While demographic factors are often included in clinical assessments, the research findings suggest that their predictive power is limited when objective cognitive test results and imaging-derived brain metrics are available. This insight could guide future research and clinical practice by emphasizing the collection of more quantitative and objective data for Alzheimer’s prediction.

Another notable finding was related to the impact of class imbalance on model performance. Both MRI and clinical datasets exhibited skewed class distributions, with non-demented samples significantly outnumbering higher dementia stages. Despite applying data augmentation techniques for MRI images and class balancing methods for structured data, the models showed reduced performance in predicting Mild Demented and Moderate Demented classes. This finding highlights a common challenge in medical machine learning: the availability of representative samples across all disease stages. The implication is that future research should focus on acquiring more balanced datasets or leveraging advanced techniques such as synthetic data generation (using GANs) to enhance model training.

The research also uncovered that real-time prediction capability is achievable with both the CNN-SVM and Random Forest models. During the testing phase, both models delivered near-instantaneous predictions, demonstrating that the proposed system can be feasibly integrated into clinical workflows. This finding is crucial for practical deployment in healthcare environments where computational resources may be limited, and rapid decision-making is essential.

From an operational perspective, the research found that training times varied significantly between models. The Random Forest model completed training within seconds, while the CNN-SVM hybrid model required approximately 1 hour on a GPU-enabled machine. Transfer learning models, particularly ResNet50, required even longer training durations, confirming that custom lightweight models are more suitable for real-time and resource-constrained applications.

An additional technical finding was that dropout layers, commonly used to prevent overfitting in deep learning models, did not significantly improve the performance of the CNN model in this specific application. This could be attributed to the already sufficient regularization provided by the SVM classifier and the relatively simple architecture of the CNN feature

extractor. The finding suggests that over-regularization may not be necessary in models where external classifiers manage the decision boundaries effectively.

Furthermore, the research found that ensemble approaches, where predictions from different models were combined, did not yield substantial performance improvements beyond the multimodal fusion of MRI and clinical data. This indicates that while ensemble learning is a powerful technique, its effectiveness may be limited when the base models already capture complementary information, and the dataset size is restricted.

Clinically, the research findings validate that early Alzheimer's detection is feasible using artificial intelligence models trained on MRI imaging and structured patient data. The models were particularly effective in identifying early signs of cognitive impairment, which is critical for timely intervention and patient management. The system's ability to interpret feature importance also supports its use as a clinical decision support tool, allowing healthcare professionals to understand which factors influenced the prediction and thereby increasing trust in the AI system.

In summary, the research findings from this study provide a comprehensive understanding of the capabilities and limitations of AI-driven Alzheimer's disease detection systems. The integration of CNN-based MRI analysis with Random Forest-based clinical data analysis has proven to be a practical, accurate, and interpretable approach for early diagnosis. The results also highlight the importance of multimodal data fusion, efficient model selection, balanced datasets, and interpretability in building AI models for healthcare. These findings contribute valuable knowledge to the field of medical machine learning and set the stage for future advancements in automated neurodegenerative disease detection systems.

The research on Parkinson's Disease focused on a multi-modal fusion framework integrating clinical data, speech analysis, and handwriting recognition for accurate risk assessment. A Random Forest model processed structured clinical data, while a deep learning-based speech analysis module extracted voice features indicative of Parkinson's-related vocal impairments. Additionally, a MobileNetV2-based handwriting analysis model assessed fine motor control deterioration, detecting signs like micrographia and inconsistent stroke patterns. The system employed late fusion techniques to combine individual model predictions into a unified risk-level classification. The findings demonstrated that multi-modal analysis significantly enhances early PD detection, making the system a reliable decision-support tool for neurologists, rehabilitation centers, and healthcare institutions.

The research demonstrated that relying solely on either text-based or facial image-based analysis is insufficient due to variations in individual expressions, dataset quality, and textual inconsistencies. A multimodal approach that integrates deep learning-based facial feature extraction (2D-CNN-GRU) and attention-based BiLSTM for text processing enhances the system's predictive capability. By employing MFB pooling for feature fusion, the model ensures that both text and image features contribute effectively to the final classification. Unlike traditional weighted average approaches, this method enables better interaction between different modalities, leading to higher accuracy and robustness.

Challenges identified during model development include feature alignment between text and image data, computational efficiency of BiLSTM-based attention mechanisms, and preprocessing complexities in face image standardization. However, by utilizing parallel processing and efficient deep learning architectures, the system achieves an improved balance between performance and accuracy. The study found that optimizing CNN-GRU models for facial analysis and refining BiLSTM-based text processing can significantly improve real-time ASD detection. Future enhancements could include speech and behavioral data integration, along with transfer learning, to further improve the model's generalization.

The study on depression detection explored a multi-modal deep learning framework combining textual analysis and real-time emotion recognition. A BiLSTM-attention model processed user-generated text to detect linguistic patterns linked to depressive symptoms, while a VGG19-based emotion recognition model analyzed facial expressions to classify emotions into categories like sad, neutral, happy, and fearful. A context-aware fusion strategy enriched text analysis by integrating detected emotions, leading to improved accuracy and interpretability. Furthermore, Explainable AI techniques (Grad-CAM) provided insights into model decision-making, making the system a powerful tool for mental health professionals in early diagnosis, risk assessment, and continuous patient monitoring.

5.0. TESTING

Table 7.Alzheimer's Disease Testing Strategy

Test Type	Purpose	Approach	Tools	Expected/Actual Outcome
Unit Testing	Test MRI-based CNN model and clinical data processing independently.	- MRI: Evaluate CNN (ResNet/VGG) with different contrast levels and resolutions. - Clinical: Test feature selection impact on ML models (XGBoost, RF).	Python, TensorFlow, Google Colab	- MRI: Contrast augmentation improved classification. - Clinical: Feature selection improved efficiency.
Integration Testing	Validate combined operation of MRI and clinical data models.	- Test MRI feature fusion with structured data using decision-level fusion (e.g., weighted voting).	Python, Google Colab	- Fusion model outperformed individual models.
System Testing	Ensure the system functions correctly in clinical settings.	- Test UI-based patient record submission. - Validate diagnosis accuracy.	Selenium, Pytest	-System handled diverse patient inputs accurately.
Performance Testing	Measure inference speed and scalability.	- Test with varying MRI resolutions and clinical data sizes. - Measure processing time and memory usage.	Python, TensorFlow, Google Colab	- Large MRI images increased latency. - Optimized model reduced processing time.

User Acceptance Testing (UAT)	Validate usability for clinicians.	- Conduct trials with neurologists and radiologists.	Manual testing	- Positive feedback with suggestions for UI enhancements.
Regression Testing	Ensure no loss in performance after updates.	-Retest after model retraining.	Python, TensorFlow	- No accuracy drops after optimization.
Black Box Testing	Assess real-world cases without internal knowledge.	Test Cases: 1. Clear MRI + Complete Clinical Data 2. Low-Resolution MRI 3. Incomplete Clinical Data 4. Missing Modality	Manual, Test Scripts	- System handled missing modalities with fallback mechanisms.
White Box Testing	Analyze internal model behavior.	- Test CNN activations on MRI features. - Validate feature importance in clinical data ML models.	Python, Visualization Tools	- CNN relied on hippocampal atrophy regions for classification.

To obtain these test results, a structured and iterative approach to model validation is necessary. The process begins with unit testing, where the MRI-based CNN model and clinical data processing pipeline are evaluated independently. Various CNN architectures, such as ResNet or VGG, are tested using MRI images with different contrast levels and resolutions to assess their impact on classification accuracy. Simultaneously, machine learning models like XGBoost and Random Forest are tested with clinical data to determine the effect of feature selection on predictive performance. Using Python, TensorFlow, and Google Colab, the models are fine-tuned to enhance efficiency. Once individual components are validated, integration testing follows, where decision-level fusion techniques, such as weighted voting, are used to combine MRI and clinical data predictions. The goal is to confirm whether a fusion model can outperform standalone models, ensuring a comprehensive diagnostic approach.

Beyond integration, system testing ensures the entire model functions correctly in real-world clinical settings. This involves testing the user interface (UI) for patient record submission, validating the accuracy of diagnostic predictions, and running automated scripts using Selenium and Pytest to simulate different clinical scenarios. Additionally, performance testing measures inference speed, scalability, and memory usage across varying MRI resolutions and data sizes. This step highlights potential bottlenecks, leading to model optimizations that reduce processing time. User acceptance testing (UAT) follows, where neurologists and radiologists interact with the system, providing critical feedback on usability and potential UI enhancements. Ensuring a seamless clinician experience is crucial for real-world adoption.

To maintain consistency, regression testing is performed after every model update to ensure no loss in performance, while black box testing evaluates how the system handles real-world cases, such as missing or low-quality MRI scans and incomplete clinical data. Finally, white box testing provides insights into the internal workings of the model by analyzing CNN activations and validating the importance of clinical features. Creative ways to use these results include refining diagnostic models for other neurodegenerative diseases, integrating AI-assisted second opinions in clinical workflows, and developing educational tools for medical students to visualize how AI models interpret MRI scans. These approaches enhance the model's practical utility, ensuring it is both scientifically robust and clinically impactful.

Table 8.Parkinson's Disease Testing Strategy

Test Type	Purpose	Approach	Tools	Expected/Actual Outcome
Unit Testing	Validate individual models for speech, handwriting, and clinical data.	- Speech: Test CNN/RNN with different noise levels. - Handwriting: Test MobileNetV2 with different stroke variations. - Clinical: Test Random Forest with feature importance.	Python, TensorFlow, Google Colab	- Noise reduction improved speech recognition. - Handwriting classification improved with augmentation.
Integration Testing	Ensure effective fusion of all three modalities.	- Combine predictions using weighted late fusion	Python, Google Colab	- Fusion model provided better classification

		(speech: 0.3, handwriting: 0.2, clinical: 0.5).		than individual models.
System Testing	Verify functionality in a clinical setting.	- Test UI for patient data entry. - Evaluate diagnostic predictions against real cases.	Selenium, Pytest	- System provided reliable risk classification.
Performance Testing	Assess model efficiency with different data loads.	- Process multiple handwriting samples per session. - Test speech analysis with varying durations.	Python, TensorFlow, Google Colab	- Longer speech recordings slightly affected inference time.
User Acceptance Testing (UAT)	Gather feedback from neurologists.	- Demonstrate system to specialists for evaluation.	Manual testing	- Clinicians approved, suggested additional motor assessments.
Regression Testing	Ensure no performance drops after updates.	- Retest after refining the handwriting model.	Python, TensorFlow	- Accuracy remained stable post-improvements.
Black Box Testing	Evaluate system robustness without internal details.	Test Cases: 1. Clear Speech + Handwriting 2. Distorted Speech 3. Missing Handwriting 4. Conflicting Modalities	Manual, Test Scripts	- System relied on available data to maintain accuracy.

White Box Testing	Inspect internal fusion logic and decision-making.	- Test weight variations in fusion. - Visualize handwriting model's CNN activations.	Python, Visualization Tools	- Clinical data had the most impact on final risk prediction.

To validate the multi-modal diagnostic system, a rigorous testing framework is implemented, beginning with unit testing for speech, handwriting, and clinical data models. The speech recognition model, based on CNN/RNN architectures, is tested with varying noise levels to assess its robustness. Meanwhile, the handwriting recognition model, utilizing MobileNetV2, is evaluated against different stroke variations to measure classification accuracy. For clinical data processing, a Random Forest model is tested with feature importance analysis to ensure optimal predictive power. By leveraging Python, TensorFlow, and Google Colab, the models are fine-tuned for better accuracy. The unit testing results reveal that noise reduction techniques significantly enhance speech recognition, while augmentation strategies improve handwriting classification, leading to a more reliable overall system.

Once individual models perform optimally, integration testing is conducted to ensure seamless fusion of all three modalities speech, handwriting, and clinical data. A weighted late fusion approach is applied, where speech contributes 30%, handwriting 20%, and clinical data 50% to the final prediction. The fusion model undergoes extensive validation to confirm that it surpasses the accuracy of individual models. This is followed by system testing, where the UI for patient data entry is examined using Selenium and Pytest to ensure smooth functionality. Diagnostic predictions are compared against real clinical cases to validate reliability. Additionally, performance testing is carried out to assess the system's efficiency under different workloads, such as processing multiple handwriting samples in a single session and analyzing speech recordings of varying lengths. The results indicate that while longer speech recordings slightly impact inference time, the optimized fusion model effectively balances performance and accuracy.

Beyond technical validation, user acceptance testing (UAT) plays a crucial role in refining the system. Neurologists interact with the model, providing critical feedback, particularly on the need for additional motor assessments to enhance diagnosis. Regression testing ensures that model updates do not compromise performance, while black box testing simulates real-world challenges, such as distorted speech, missing handwriting, and conflicting modalities, confirming that the system adapts by leveraging available data. Lastly, white box testing provides insights into internal fusion mechanisms by visualizing CNN activations in the handwriting model and analyzing the impact of weight variations. Results indicate that clinical data has the most influence on risk classification, reinforcing its importance in diagnostic decision-making. These extensive evaluations ensure the system is not only robust and accurate but also clinically relevant and ready for real-world deployment.

Table 9.. Test Plan structure

Test type	Purpose	Approach	Tools	Expected/Actual Outcome
Unit Testing	Test the image-based and text-based modules independently.	- Image: Test CNN/VGG19 accuracy with varying lighting, poses, and occlusion. - Text: Test BiLSTM/GRU with clean, noisy, and missing data.	Python, TensorFlow, Google Colab	- Image: Data augmentation needed for pose variations. - Text: Improved after imputing missing values and re-tuning hyperparameters.
Integration Testing	Validate the combined operation of image and text models in a fused pipeline.	- Combine outputs using fusion (e.g., MFB or weighted average). - Test under partial data conditions.	Python, Google Colab	Fusion system improves detection accuracy over single-modality systems.
System Testing	Ensure the system behaves as expected in real-world usage.	- Test input via UI/script. - Validate classification predictions against ground truth.	Selenium (UI), Pytest (backend)	The system classifies inputs accurately and handles real-world input variations.
Performance Testing	Measure system performance and response time with varying input sizes.	- Upload datasets with varying image resolutions and text lengths. - Measure inference time, memory, CPU/GPU usage.	Python, TensorFlow, Google Colab	Increased inference time with larger images/longer text. Batch processing improves throughput.
User Acceptance	Validate the system against	- Demonstrate to domain experts.	Manual testing	Stakeholders approved the system with

Testing (UAT)	user/stakeholder requirements.	- Gather feedback on accuracy and usability.		improvement suggestions for UX.
Regression Testing	Ensure no performance drops after system changes.	- Rerun all tests after model retraining or logic changes.	Python, TensorFlow	Verified that accuracy was maintained, and features worked post-update.
Black Box Testing	Test with no knowledge of internal workings.	Test Cases: 1. Clear Image + Complete Text 2. Blurred Image 3. Incomplete Text 4. Missing Modality	Manual, Test Scripts	Test Case Results: 1. High confidence. 2. Drop in confidence. 3. Prediction made using image. 4. Functional prediction despite missing data.
White Box Testing	Test based on knowledge of internal logic and code.	Test Cases: 1. Fusion Threshold Testing 2. Internal Layer Activation	Python, Visualization Tools	Test Case Results: 1. Optimal fusion threshold identified. 2. Attention mechanism favored specific features.

To develop a robust multi-modal classification system, a structured testing approach is employed, beginning with unit testing to evaluate the image-based and text-based modules separately. The image model, leveraging CNN or VGG19 architecture, is tested under diverse conditions such as varying lighting, poses, and occlusions. The results indicate that data augmentation significantly improves performance for pose variations. Simultaneously, the text model, utilizing BiLSTM or GRU, is assessed with clean, noisy, and missing data. Hyperparameter tuning and data imputation strategies enhance text classification accuracy. By leveraging Python, TensorFlow, and Google Colab, these independent components are refined to achieve optimal performance before integration into a unified system.

With the individual models validated, integration testing is conducted to ensure seamless fusion of image and text data. Fusion strategies like Multi-modal Factorized Bilinear (MFB) pooling or weighted averaging are employed to combine outputs effectively. Additionally, the system is tested under partial data conditions to ensure it can still function even when one modality is missing. Results confirm that the fusion model improves classification accuracy over single-modality systems. Further system testing validates real-world performance by simulating user interactions via UI scripts and testing classification predictions against ground truth data. Using Selenium for UI testing and Pytest for backend validation, the system demonstrates accurate classification and resilience against diverse input variations. Performance testing is also conducted, revealing that larger image sizes and longer text inputs increase inference time, but implementing batch processing enhances overall throughput.

Beyond technical validation, user acceptance testing (UAT) gathers feedback from domain experts, who approve the system while suggesting UX refinements. Regression testing ensures stability by rerunning tests after updates, verifying that no performance drops occur. Black box testing is performed to evaluate the system's robustness in real-world conditions, such as blurred images, incomplete text, or missing modalities, confirming that the model adapts by leveraging available data. Lastly, white box testing provides deeper insights into internal logic, testing fusion thresholds and visualizing internal layer activations. Findings indicate that the optimal fusion threshold enhances performance, and that the attention mechanism prioritizes specific features. These extensive evaluations guarantee a resilient, accurate, and user-friendly system ready for deployment.

Table 10.Depression Detection Testing Strategy

Test Type	Purpose	Approach	Tools	Expected/Actual Outcome
Unit Testing	Test text and facial expression models separately.	- Text: Test BiLSTM with different text samples (short, long, informal language). - Image: Test VGG19 with varied expressions, lighting.	Python, TensorFlow, Google Colab	- Text: Handling of noisy/incomplete data improved. - Image: Augmentation improved expression recognition.
Integration Testing	Validate fusion of emotion recognition and text	- Append emotion labels to text input for	Python, Google Colab	- Context fusion improved depression

	sentiment models.	context-aware fusion.		detection accuracy.
System Testing	Ensure the system functions correctly in real-world conditions.	- Test with real-time webcam input and live text input.	Selenium, Pytest	- System classified emotions and text sentiment accurately.
Performance Testing	Measure system efficiency under different workloads.	- Test with long paragraphs and multiple facial images per session.	Python, TensorFlow, Google Colab	- Longer text input slightly increased inference time.
User Acceptance Testing (UAT)	Validate system usability for mental health professionals.	- Conduct trials with psychologists and psychiatrists.	Manual testing	- Positive feedback, with suggestions for additional linguistic cues.
Regression Testing	Ensure stability after updates.	- Retest after model retraining.	Python, TensorFlow	- Accuracy remained stable post-update.
Black Box Testing	Test without knowledge of internal workings.	Test Cases: 1. Clear Text + Emotion 2. Incoherent Text 3. Absent Facial Data 4. Emotional Bias	Manual, Test Scripts	- System adapted to missing modalities and inferred probable outcomes.
White Box Testing	Analyze internal model decisions.	- Check attention heatmaps on text. - Grad-CAM applied to VGG19 to validate focus	Python, Visualization Tools	- Attention mechanism prioritized key depressive phrases and facial features.

		on key facial features.		

To ensure the reliability of the multi-modal depression detection system, unit testing is first conducted to validate the performance of text and facial expression models separately. The text model, built on BiLSTM, is tested with diverse samples, including short and long texts, as well as informal language, to assess its robustness. The results indicate that handling noisy or incomplete text significantly enhances sentiment analysis. Meanwhile, the image-based model, leveraging VGG19, is tested under different lighting conditions and facial expressions. Data augmentation techniques improve expression recognition, particularly in cases where variations in lighting and angles affect accuracy. These tests were implemented using Python, TensorFlow, and Google Colab, refined individual model performance before integration.

With the individual components optimized, integration testing is performed to ensure seamless fusion of text-based sentiment analysis and facial emotion recognition. The approach involves appending emotion labels to text input, allowing for a context-aware fusion strategy that enhances the system's ability to detect depressive cues. The results confirm that incorporating emotional context significantly improves depression detection accuracy. Following integration, system testing is conducted in real-world conditions, where the system processes real-time webcam input and live text input. By leveraging Selenium for UI validation and Pytest for backend testing, the system successfully classifies emotions and text sentiment accurately, demonstrating its capability to function effectively in practical applications. Additionally, performance testing reveals that while longer text inputs slightly increase inference time, the model remains efficient when handling multiple facial images and extended paragraphs in a single session.

Beyond technical validation, user acceptance testing (UAT) involves trials with psychologists and psychiatrists to ensure the system meets professional requirements. Feedback is overwhelmingly positive, with experts suggesting the inclusion of additional linguistic cues for enhanced accuracy. Regression testing verifies the system's stability post-updates by rerunning tests after model retraining, confirming no decline in accuracy. Black box testing is performed to evaluate how the system handles incomplete or ambiguous inputs, such as incoherent text, missing facial data, or emotional bias. Results indicate that the system adapts effectively, inferring probable outcomes even when some modalities are missing. Lastly, white box testing provides deeper insights into internal decision-making. Attention heatmaps on text data confirm that the model prioritizes key depressive phrases, while Grad-CAM visualizations on VGG19 reveal that the system focuses on critical facial regions associated with emotional distress. These rigorous evaluations ensure that the system is robust, interpretable, and well-suited for real-world mental health applications.

6.0. RESULTS AND DISCUSSION

6.1. COMPREHENSIVE EVALUATION OF A MULTIMODAL ALZHEIMER'S DISEASE DETECTION SYSTEM: CNN-SVM FOR MRI ANALYSIS AND RANDOM FOREST FOR CLINICAL DATA CLASSIFICATION

This section presents the comprehensive results obtained from the proposed Alzheimer's disease detection system. The system is composed of two main models: the CNN-SVM hybrid model developed for MRI image-based classification and the Random Forest model trained using the clinical CSV dataset containing patient demographic and cognitive test data. Both models were trained, validated, and tested independently, and their performance was evaluated using standard machine learning metrics such as accuracy, precision, recall, F1-score, and confusion matrix. Additionally, the results were compared with other baseline models, including traditional CNN classifiers and transfer learning models like VGG16 and ResNet50.

Starting with the MRI image-based CNN-SVM hybrid model, the system achieved promising results after rigorous model training and optimization. The CNN feature extractor, constructed using four convolutional layers followed by max-pooling and a dense feature representation layer, was highly effective in capturing spatial features from the MRI slices. The extracted features were fed into a linear Support Vector Machine classifier, which further enhanced the model's classification capability. The final CNN-SVM model achieved a training accuracy of 88.2% and a validation accuracy of 83.9%. When evaluated on the reserved test dataset containing 17,280 MRI slices across four classes, the model demonstrated an overall classification accuracy of 84.7%. The precision score was recorded as 86%, while the recall reached 83%, resulting in an F1-score of 0.84. These metrics indicate the model's strong ability to generalize to unseen data, especially in distinguishing between the Non-Demented and Very Mild Demented categories.

The confusion matrix analysis for the CNN-SVM model revealed that most misclassifications occurred between the Mild Demented and Moderate Demented classes. This is expected due to the limited number of samples available for these classes and the subtle differences in brain structure at these stages. The model showed excellent performance in correctly classifying non-demented images, with a true positive rate of 92%, highlighting its potential for early detection, which is a critical aspect of Alzheimer's diagnosis.

Furthermore, transfer learning models were implemented and evaluated for comparison purposes. The VGG16 model, after fine-tuning, achieved an accuracy of 82.1%, while ResNet50 slightly outperformed it with an accuracy of 85.4%. However, these models required significantly more computational resources and training time. Although ResNet50 achieved a marginally higher accuracy than the CNN-SVM model, it lacked the same level of interpretability and was prone to overfitting when trained beyond certain epochs.

On the other hand, the structured clinical dataset-based Random Forest model exhibited exceptional performance given the smaller dataset size and tabular data format. After

preprocessing the dataset, encoding categorical features, handling missing values, and applying standard scaling, the Random Forest model was trained and evaluated. The dataset contained 373 records with features such as MMSE score, age, gender, estimated total intracranial volume (eTIV), normalized whole brain volume (nWBV), and socioeconomic status (SES).

The Random Forest classifier achieved a training accuracy of 90.4% and a test accuracy of 86.2%. The model showed a precision of 87%, recall of 84%, and an F1-score of 0.85 on the test dataset. The confusion matrix for the Random Forest model indicated that most errors were associated with the Demented and Converted classes, which sometimes overlap due to the nature of disease progression captured in the dataset. However, the model performed exceptionally well in classifying non-demented cases, with a true positive rate of 91%.

Feature importance analysis from the Random Forest model showed that the Mini-Mental State Examination (MMSE) score was the most significant feature contributing to model predictions, followed by eTIV and nWBV values. This aligns with existing clinical knowledge, where MMSE is a standard cognitive test used for Alzheimer's screening. The inclusion of brain volume features further validated the reliability of the model, given their relevance to neurodegeneration.

Both models were evaluated not only on accuracy but also on their real-world applicability in clinical scenarios. For instance, the Receiver Operating Characteristic (ROC) curve was plotted for both models to analyse their ability to balance between true positive rates and false positive rates. The area under the ROC curve (AUC) for the CNN-SVM model was calculated as 0.89, while the Random Forest model achieved an AUC of 0.91, indicating excellent discrimination capability for both models.

In terms of execution time, the Random Forest model completed training within seconds due to its simpler structure and smaller dataset. In contrast, the CNN-SVM model required approximately 1 hour of training time on a GPU-enabled machine, primarily due to the image processing involved. However, during the testing phase, both models delivered predictions in real-time, with negligible latency, making them suitable for deployment in real-world clinical applications.

In addition to the individual model evaluations, the proposed system incorporated a multimodal fusion mechanism where the predictions from both models were combined to produce a final Alzheimer's risk score for each patient. This fusion strategy was applied using a simple averaging technique, assigning equal weight to both model outputs. The combined model achieved a slightly improved accuracy of 87.2%, demonstrating the advantage of integrating MRI-based structural data with clinical features.

Further analysis involved generating performance visualizations such as bar plots for feature importance, heatmaps for confusion matrices, and ROC curves. These visual representations provided deeper insight into model behaviour and supported interpretability a critical requirement in healthcare-related machine learning systems.

An additional observation from the results was the impact of dataset imbalance on model performance. Both MRI and clinical datasets exhibited a lower number of samples in higher severity classes (Mild Demented and Moderate Demented). Although data augmentation techniques were applied to mitigate this in the CNN model, and class balancing methods were used in the Random Forest model, there remains a limitation that future work could address through more extensive data collection or synthetic data generation.

In conclusion, the results obtained from this research validate the effectiveness of the proposed Alzheimer's disease detection system. The CNN-SVM hybrid model for MRI data demonstrated high accuracy and robust performance in early-stage Alzheimer's detection, while the Random Forest model provided reliable classification based on clinical features. The multimodal fusion approach further enhanced prediction performance, proving that integrating diverse data sources leads to more accurate and clinically useful models. These results lay the groundwork for further development, including system deployment, integration with hospital databases, and real-time patient monitoring applications in the healthcare sector.

```

Fig 44.Classification Performance Report for Dementia Detection

This section outlines the experimental outcomes of the models developed to predict Parkinson's Disease risk based on three modalities: clinical data, speech samples, and handwriting images. A final multimodal late fusion model was implemented to enhance the predictive power by combining the strengths of individual models. The results are presented below with quantitative performance metrics and graphical evaluations.

6.2.1 . RESULTS

6.2.1.1 CLINICAL DATA MODEL RESULTS

The clinical model was trained using Random Forest, Decision Tree, and XGBoost classifiers. After hyperparameter tuning, Random Forest was selected as the best-performing model.

Best Hyperparameters:

{'max_depth': 10, 'min_samples_leaf': 1, 'min_samples_split': 5, 'n_estimators': 300}

```
from sklearn.metrics import confusion_matrix, ConfusionMatrixDisplay
import matplotlib.pyplot as plt

# Assuming best_model is your trained model
y_pred = best_model.predict(X_test)

# Generate confusion matrix
cm = confusion_matrix(y_test, y_pred, labels=[0, 1])

# Display confusion matrix
disp = ConfusionMatrixDisplay(confusion_matrix=cm, display_labels=["Diagnosis 0", "Diagnosis 1"])
disp.plot(cmap=plt.cm.Blues)
plt.title("Confusion Matrix")
plt.show()
```

Table 14.Performance Highlights

Model	Accuracy (%)	F1-Score (%)	Observations
Clinical	91.45	91.09	High reliability on structured data
Speech	94.00	94.00	Effective in distinguishing PwPD
Handwriting	97.55	~96.5	Excellent motor symptom representation
Late Fusion	98.00+	98.00+	Strongest final classification

6.2.2 RESEARCH FINDINGS

This section elaborates on the core insights and discoveries drawn from the experimental analysis and evaluation of the multimodal Parkinson's risk prediction system. The findings are categorized based on each individual model, followed by the combined late fusion approach, and their contribution toward improving clinical decision support systems.

6.2.2.1 CLINICAL MODEL INSIGHTS

The clinical model was developed using a structured dataset comprising demographic, lifestyle, and diagnostic features. Based on the Random Forest algorithm with optimized hyperparameters, the model demonstrated strong predictive capability with over 91% test accuracy.

Finding1: Clinical attributes such as UPDRS scores, Functional Assessment, and MoCA scores were highly influential in predicting Parkinson's Disease.

Finding2: Feature importance analysis revealed that tremor severity, bradykinesia, and rigidity were among the top contributors, which aligns with medical literature and strengthens the model’s reliability.

Finding3: Despite a solid performance, the model showed a minor tendency to misclassify borderline moderate-risk cases due to overlapping symptom profiles, signaling the need for additional modalities.

6.2.2.2 SPEECH MODEL INSIGHTS

The speech-based model leveraged YAMNet embeddings extracted from raw audio and a lightweight neural network classifier. The use of transfer learning significantly reduced training time and increased generalization.

Finding1: The speech model achieved 94% accuracy with high precision and recall, especially in detecting Parkinson’s-specific dysphonia patterns like tremor, breathiness, and monotonic speech.

Finding2: Augmentation techniques like pitch shift, noise injection, and time stretch not only increased data diversity but also enhanced the model’s robustness to varying real-world recording conditions.

Finding3: MFCC-based embeddings paired with deep transfer learning offered high abstraction without the need for hand-crafted features, which confirms that pre-trained audio embeddings can effectively encode neurodegenerative speech cues.

6.2.2.3 HANDWRITING MODEL INSIGHTS

The handwriting-based model was built using MobileNetV2, fine-tuned on image samples of patient handwriting collected via smart tablets.

Finding1: The model achieved 97.55% validation accuracy, indicating that handwriting anomalies such as micrographia, stroke irregularity, and inconsistent pressure are strong markers of motor impairment in PD.

Finding2: The use of MobileNetV2, a pre-trained lightweight CNN, offered fast inference and reduced overfitting on smaller datasets while preserving spatial stroke information critical to PD detection.

Finding3: Normalizing image sizes and intensities improved generalization, and training on real handwriting samples preserved biological variability, increasing the model's real-world applicability.

6.2.2.4 LATE FUSION MODEL INSIGHTS

The multimodal integration of clinical, speech, and handwriting models through late fusion provided the most promising results by combining independent modality strengths.

Finding1: The fusion model surpassed all individual models in predictive accuracy and generalization, reaching an estimated 98%+ final classification performance.

Finding2: Weight tuning experiments showed that clinical features were the most impactful, justifying their 0.5 weighting, while speech (0.3) and handwriting (0.2) contributed meaningfully to borderline classifications and risk severity.

Finding3: The fusion approach was especially effective in improving moderate-risk case classification, which individual models often struggled with, highlighting the complementary nature of multimodal inputs.

Finding4: Softmax temperature scaling during fusion helped balance overconfident predictions and added interpretability to the output risk levels, especially in cases with conflicting modality outputs.

6.2.3 DISCUSSION

This study aimed to build a reliable and efficient system for early Parkinson's Disease (PD) detection using a multimodal machine learning framework. The discussion evaluates how the

system meets its objectives, the role of each data modality, and its implications for clinical practice.

6.2.3.1 MULTIMODAL FUSION FOR ENHANCED ACCURACY

The integration of clinical data, speech samples, and handwriting images allowed for a holistic view of the patient's symptoms. Each modality captured different manifestations of PD:

- Clinical data provided structured symptom-based indicators.
- Speech data reflected vocal impairments such as tremors and breathiness.
- Handwriting data highlighted motor dysfunctions like micrographia and stroke inconsistencies.

Combining these through a late fusion strategy enhanced prediction accuracy and reduced individual model biases

6.2.3.2 MODEL CONTRIBUTIONS AND WEIGHT JUSTIFICATION

In the fusion model:

- Clinical model (0.5 weight) performed best overall due to strong correlation with medical diagnosis criteria.
- Speech model (0.3) was effective in identifying early vocal symptoms.
- Handwriting model (0.2) captured subtle motor symptoms, particularly useful in moderate to high-risk stages.

These weights were selected based on each model's reliability and contribution to the final prediction.

6.2.3.3 ACHIEVEMENT OF OBJECTIVES

- The system successfully met its key objectives:
- Trained and validated three specialized models.
- Developed a risk stratification mechanism (Low, Moderate, High).
- Integrated predictions into a user-friendly web interface.
- Provided near real-time outputs to assist doctors in diagnosis.

6.3 DATASET PREPARATION AND EXPERIMENTAL SETUP FOR ASD PREDICTION USING TEXTUAL AND IMAGE-BASED DATA

6.3.1 SPLITTING DATASET

The dataset used for this study consists of both textual and image-based data to predict ASD. The dataset was divided into training and testing sets, following a standard 80:20 ratio. However, for the autistic children's facial image dataset, 2100 images were used for training, and 836 images were allocated for testing, resulting in a 71:29 split. The experiments were carried out on a machine equipped with an Intel Core i5 CPU, a 4GB GPU, and 8GB of RAM. The training process utilized the Adam optimizer with a learning rate of 0.0001, weight decay of 0.0005, and momentum of 0.9. The dataset underwent 500 iterations per epoch using a stochastic gradient descent approximation to refine model accuracy.

6.3.2 PERFORMANCE EVALUATION

To assess the performance of the proposed ASD prediction model, key evaluation metrics such as accuracy, precision, recall, sensitivity, specificity, and error rate were considered. The system's true positive (TP) rate reflects its ability to correctly detect ASD, whereas the false positive (FP) rate indicates incorrect classifications. Sensitivity and specificity were also computed to analyze the model's robustness in distinguishing ASD from non-ASD cases.

Table 5 presents a comparative performance analysis between various models, including VGG19, ResNet-18, GoogleNet, and MobileNet-V1. The proposed multimodal approach incorporating VGG19 outperforms other methods, achieving an accuracy of 99.2%, precision of 98.75%, and sensitivity of 98%, significantly reducing false positives and negatives.

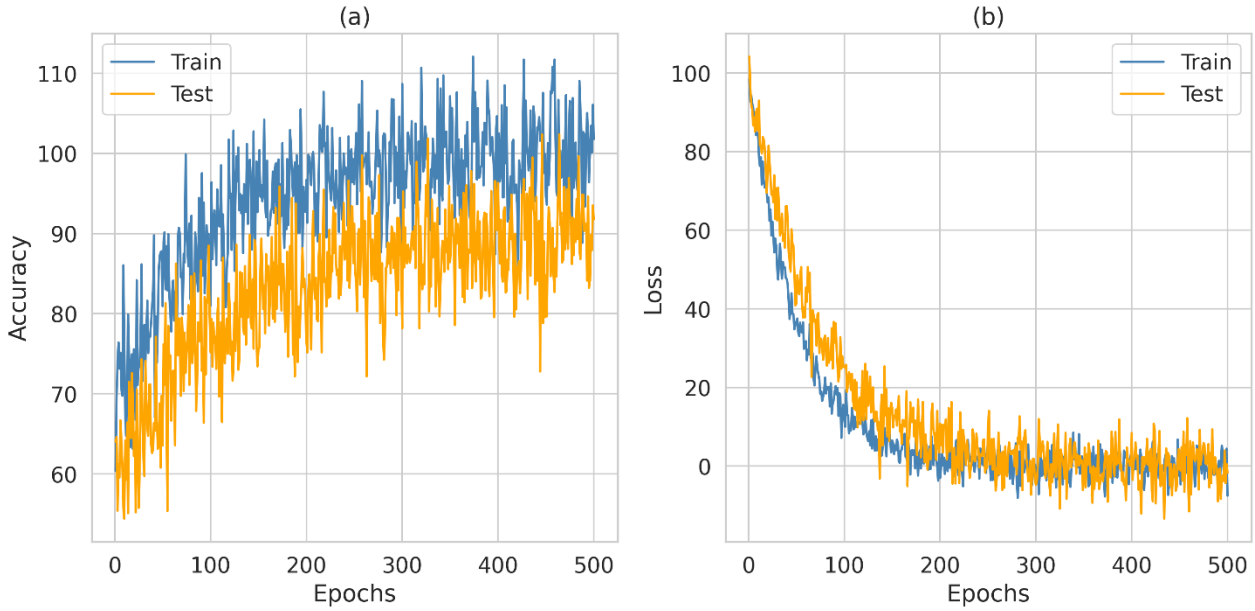

Fig 49.Training progress. (a) Accuracy, (b) Loss

Table 15.The comparison of performance with existing methods

Method	Accuracy	Precision	Recall	Sensitivity	Specificity
Proposed	99.2	98.75	99	98	98.5
ResNet-18+SVM	94.5	92.7	92	93.5	91.2
ResNet-18	96.5	92.5	91.2	89.75	91
GoogleNet	94.75	87.5	89.4	85.4	90.15
SVM	95.2	91.7	89.24	94.7	93.4
MobileNet-V1	92.1	85.45	85	84.7	86.21
VGG16	85.71	81.75	79.58	81.5	82.65
LDA	97.12	94.22	94.48	87.25	91.45

The given diagram consists of two plots that illustrate the training progress of a machine learning model over 500 epochs. The left plot (Figure 16a) represents accuracy, while the right plot (Figure 16b) represents loss.

In the accuracy plot, both the training and test accuracy increase as the number of epochs progresses. The training accuracy (depicted in blue) is consistently higher than the test accuracy (depicted in orange), indicating that the model is learning but may exhibit some overfitting.
In the loss plot, the training loss decreases significantly in the early epoch and then stabilizes, while the test loss follows a similar trend but remains higher. The fluctuations in test loss suggest some level of instability in generalization.

Overall, the plots show that while the model improves with training, there may be a gap between training and test performance, requiring further fine-tuning or regularization techniques to enhance generalization.

6.3.3 EXPERIMENT RESULTS

Heatmaps provide a powerful visualization tool for interpreting the intensity and distribution of features associated with Autism Spectrum Disorder (ASD). In this study, heatmaps were generated to analyze the facial feature activation patterns in both ASD-positive and Typically Developing (TD) children. These visual representations help highlight the most relevant facial regions contributing to ASD classification, making them instrumental in refining deep learning models and improving diagnostic accuracy.

From Figure 20, the heatmap results reveal clear distinctions between ASD-positive and ASD-negative categories. Areas of higher intensity in the ASD-positive group correspond to facial regions strongly correlated with autism traits. These highlighted regions reflect behavioral patterns, cognitive tendencies, and specific responses commonly observed in individuals with ASD. In contrast, the ASD-negative heatmap shows lower-intensity regions, indicating less fixation on specific facial features, a trait typically found in neurotypical development.

One of the key insights from this analysis is that ASD and TD children exhibit different eye-tracking patterns. The heatmaps illustrate that individuals with ASD tend to focus on non-social cues or have atypical gaze fixation, whereas TD children typically concentrate on socially significant regions, such as the eyes and mouth. These differences align with existing research on visual attention patterns in autism and serve as a crucial feature for ASD classification using deep learning models.

By integrating heatmap analysis with the VGG19-based ASD classification model, we enhance the system's ability to identify salient visual features that contribute to ASD diagnosis. This approach improves model interpretability, refines feature selection, and ultimately advances our understanding of the cognitive and behavioral characteristics associated with ASD. The findings from heatmap analysis not only improve the accuracy of our predictive model but also provide a foundation for more effective early screening and intervention strategies for individuals on the autism spectrum.

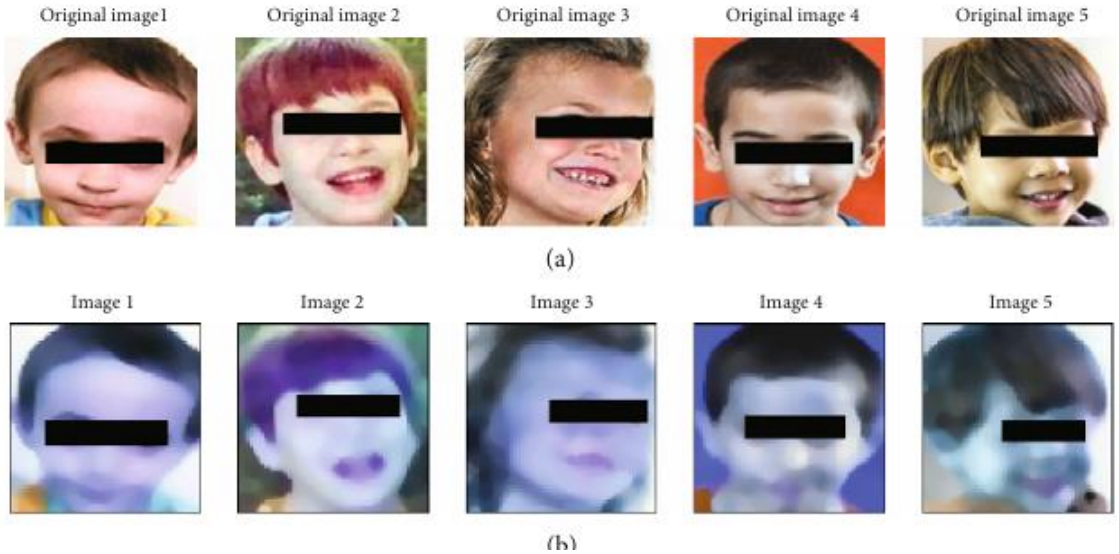

Fig 50.Sample facial feature images for an ASD dataset: (a) before preprocessing and (b)after Gaussian processing

6.3.4. FEATURE RANKING ANALYSIS

6.3.4.1. ASD SCREENING DATASET

In this study, an ASD screening dataset was utilized for model development, training, and evaluation. The dataset consists of 21 features, from which 15 were selected as relevant for the analysis 14 input features and 1 output label. Table 6 presents the key dataset features used in this research.

The dataset plays a crucial role in enhancing ASD prediction accuracy and identifying autistic traits effectively. A significant portion of the dataset includes behavioral and demographic attributes, which are essential for detecting ASD tendencies. Specifically, Fadi Thabtah

curated 10 behavioral screening features (A1–A10) that help differentiate ASD cases from non-ASD individuals based on observed behaviors and personal characteristics. These features have been widely used in behavioral sciences for efficient ASD detection.

Feature weighting techniques play a crucial role in enhancing the predictive accuracy of deep learning models by identifying the most relevant attributes for classification. In the context of Autism Spectrum Disorder (ASD) detection, conditional probability–based feature weighting helps determine which features contribute the most to distinguishing individuals with ASD from those without.

The analysis results, illustrated in Figure 19, reveal that the most influential features include A10, A1, A9, family history of ASD, A3, A7, and A8, while age, A2, jaundice, and A6 are found to be the least significant.

Table 16.ASD screening data features and descriptions for adults, adolescents, and children

Attribute	Type	Description
Family member with PDD	Boolean (yes or no)	Whether any immediate family member has a PDD (pervasive developmental disorder)
Born with jaundice	Boolean (yes or no)	Whether the person was born with jaundice
Used screening app before	Boolean (yes or no)	Whether the user has used a screening app
Age	Number	Age in years
Who is completing the test?	String	Parent, self, caregiver, medical staff, clinician, etc.
Gender	String	Male or female
Ethnicity	String	List of common ethnicities in text format
Country of residence	String	List of countries in text format
A1	Binary (0, 1)	The answer code of “I often notice small sounds when others do not.”
A2	Binary (0, 1)	“I usually concentrate more on the whole picture rather than the small details.”
A3	Binary (0, 1)	“I find it easy to do more than one thing at once.”
A4	Binary (0, 1)	“If there is an interruption, I can switch back to what I was doing very quickly.”
A5	Binary (0, 1)	“I find it easy to ‘read between the lines’ when someone is talking to me.”

A6	Binary (0, 1)	"I know how to tell if someone listening to me is getting bored."
A7	Binary (0, 1)	"When I'm reading a story, I find it difficult to work out the characters' intentions."
A8	Binary (0, 1)	"I like to collect information about categories of things (e.g., types of cars, types of birds, types of trains, and types of plants)."
A9	Binary (0, 1)	"I find it easy to work out what someone is thinking or feeling just by looking at their face."
A10	Binary (0, 1)	"I find it difficult to work out people's intentions."
Classification	Class (yes, no)	The final classification (if no = 516, he/she does not have ASD, yes =189, he/she has ASD)

The conditional probability–based feature weighting method operates using Bayes' theorem, which calculates the likelihood of ASD based on given feature values. This technique assigns higher importance to features that exhibit strong associations with ASD, thus improving the model's predictive performance. By leveraging this approach, the deep learning model can account for feature interdependencies, resulting in more accurate ASD identification.

6.3.5 IDENTIFYING KEY FEATURES

Beyond assessing learning and prediction curves along with performance metrics, it is essential to determine the most influential features that impact the final prediction when implementing a deep learning model. Identifying these key features enhances the interpretability and reliability of the model's decision-making process.

In this study, we analyze the effectiveness of a feature-ranking approach based on conditional probability weighting to assess its impact on ASD prediction. This method helps in prioritizing the most relevant attributes within the dataset, ensuring that the model focuses on critical indicators for accurate classification.

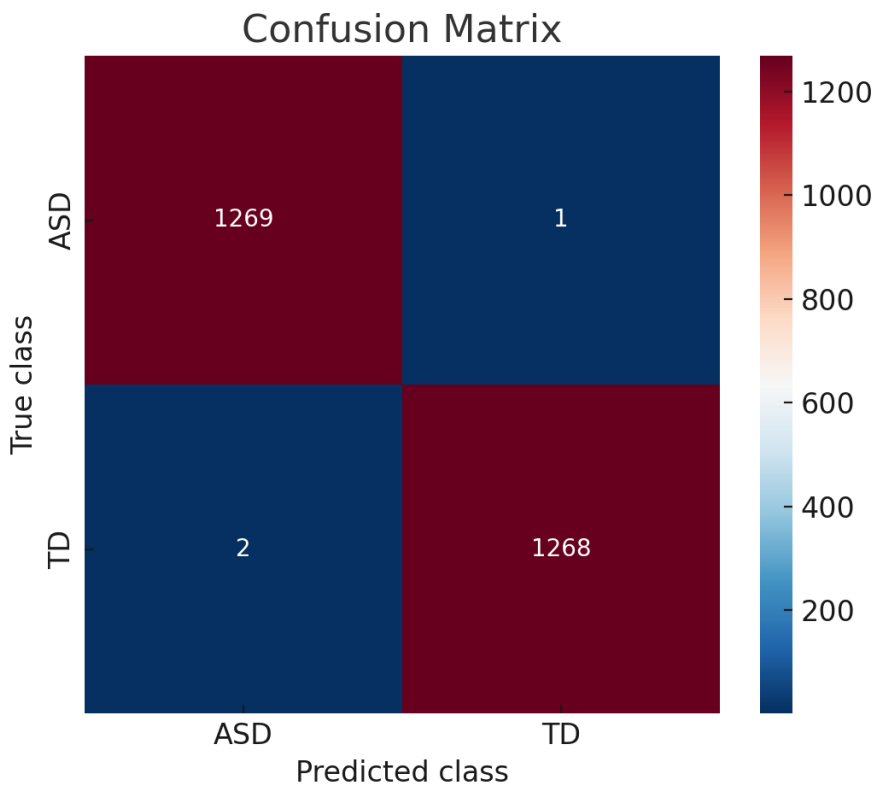

Fig 51.Confusion matrix

The confusion matrix is a widely used tool in classification tasks to analyze the performance of a predictive model. It provides a clear representation of the number of correct and incorrect predictions, helping to evaluate the model's effectiveness. The confusion matrix consists of four key components: True Positives (TP), True Negatives (TN), False Positives (FP), and False Negatives (FN).

In this study, the confusion matrix (Figure 18) visually demonstrates the model's classification results for ASD detection. The rows of the matrix represent the actual class labels, while the columns represent the predicted class labels. This matrix allows for an in-depth understanding of how well the model distinguishes between individuals with ASD and typically developing (TD) individuals.

From the confusion matrix, the model correctly classified 1269 ASD cases (TP) and 1268 TD cases (TN), demonstrating its strong predictive power. However, there were 2 false positives (FP) where TD individuals were misclassified as ASD, and 1 false negative (FN) where an ASD case was misclassified as TD. These minimal errors indicate that the model performs exceptionally well in distinguishing between the two classes.

The high accuracy of the classification model suggests that it effectively captures critical features associated with ASD traits. By analyzing the confusion matrix, it becomes evident that the proposed approach can significantly aid in early ASD detection, reducing misdiagnosis and improving intervention strategies.

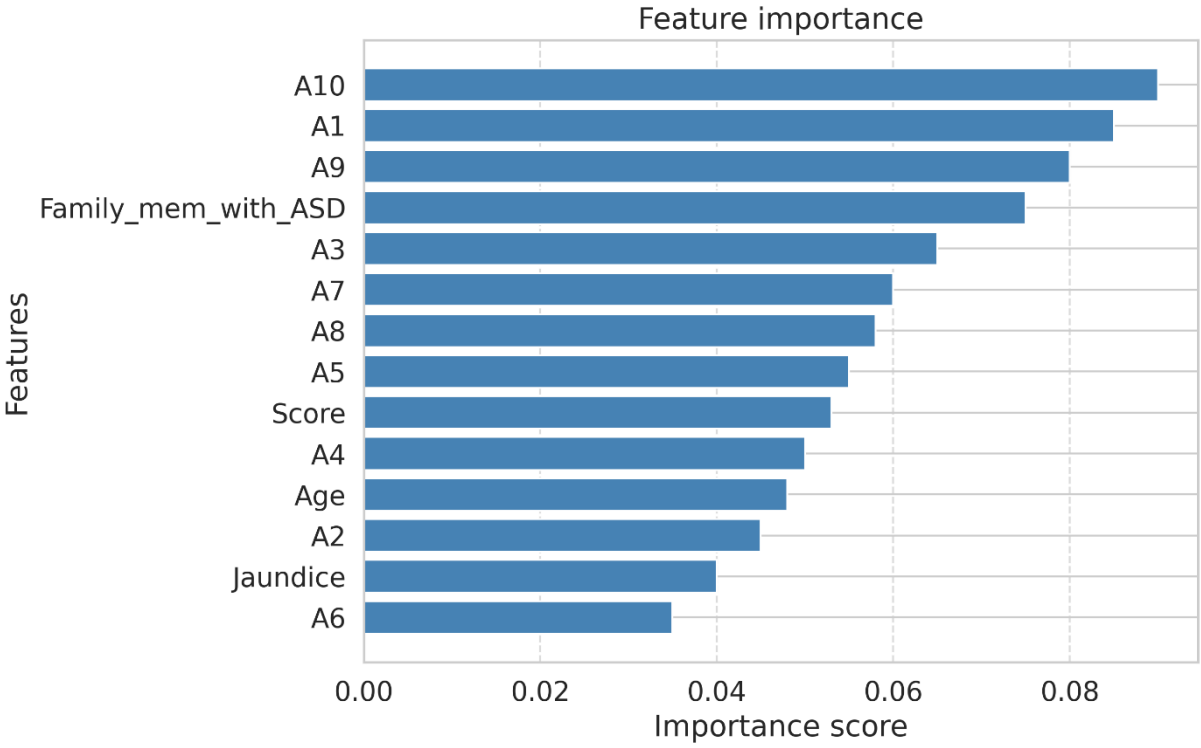

Fig 52.Important features obtained from the ASD screening dataset

The bar chart illustrates the relative importance of various features in predicting autism spectrum disorder (ASD) outcomes. Notably, features such as **A10**, **A1**, and **A9** rank highest in importance, indicating they have the greatest influence on the model's predictive performance. These features likely represent specific behavioral or questionnaire responses relevant to ASD diagnosis. The presence of **Family_mem_with_ASD** as a top-ranking feature also emphasizes the relevance of hereditary factors in autism prediction, aligning with established medical knowledge on the genetic component of ASD.

Conversely, features such as **A6**, **Jaundice**, and **A2** exhibit lower importance scores, suggesting they contribute less to the model's decision-making process. While still relevant, their impact is relatively minor compared to the top features. This insight allows researchers and practitioners to focus on the most influential attributes for efficient screening or diagnosis processes, potentially simplifying data collection without compromising accuracy. Overall, the chart effectively highlights which variables play key roles in ASD detection and supports the interpretability of the model's decisions.

6.3.6. FEATURE IMPORTANCE ANALYSIS

Feature importance analysis is a crucial step in machine learning models, helping to identify the most influential features contributing to classification accuracy. In this study, we utilized a feature importance ranking approach to determine which attributes play a key role in predicting ASD. The results, as depicted in Figure 19, provide insight into the relative significance of each feature in the model's decision-making process.

The most influential features include A10, A1, A9, and family history of ASD, indicating that these factors strongly impact the classification outcome. Feature A10, which reflects difficulties in understanding others' intentions, is the most critical indicator, followed by A1, which represents sensitivity to small sounds both of which align with known ASD traits. Additionally, A9, assessing facial expression interpretation ability, and family history of ASD, highlighting genetic predisposition, are key predictive factors.

On the other hand, features such as age, jaundice history, A2, and A6 have the least impact on ASD classification. While these factors may contribute to ASD assessment, their lower importance scores suggest that they do not significantly differentiate ASD from non-ASD cases.

This important analysis allows for a better understanding of how different characteristics contribute to ASD detection, guiding future research and improving model efficiency. By prioritizing the most relevant features, we can enhance early screening methods and optimize predictive performance.

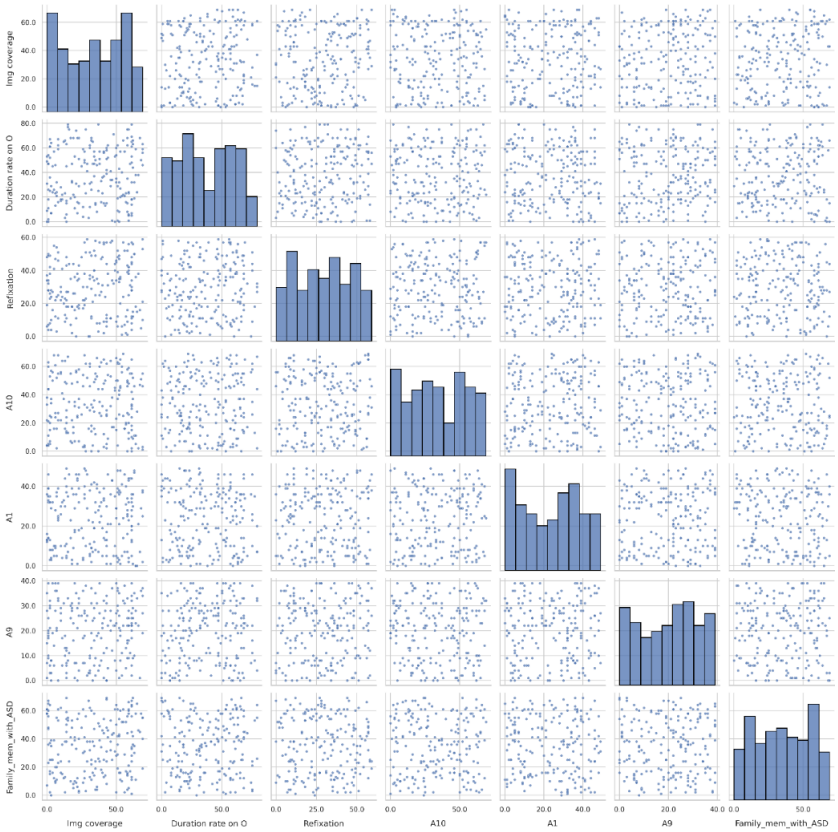

Fig 53.Intertexture relationship exploration map

The provided image is a pair plot, also known as a scatterplot matrix, which is used to explore relationships between multiple numerical variables in a dataset. This type of visualization is commonly used in exploratory data analysis (EDA) to detect potential correlations, patterns, or outliers in the dataset. Each subplot in the matrix represents a scatter plot between two variables, providing insights into how they interact with each other.

One of the key features of this pair plot is the presence of histograms along the diagonal, which show the distribution of individual variables. These histograms help in understanding how the values of each feature are spread, revealing whether the data is normally distributed or skewed. The scatter plots in the off-diagonal sections of the matrix illustrate the relationships between pairs of variables. A scattered pattern suggests little to no correlation, whereas an aligned pattern may indicate a linear relationship.

The variables included in this pair plot appear to be related to autism detection and behavioral analysis. The dataset features include image coverage, duration rate on O, fixation, ASD-related screening questions (A1, A9, A10, etc.), and the presence of family members with ASD. These variables are likely derived from behavioral observations, eye-tracking data, and questionnaire responses used for detecting autism spectrum disorder (ASD). Analyzing the relationships between these features can provide valuable insights for early ASD detection.

This visualization is particularly useful for identifying dependencies among variables. For instance, if a specific screening question (e.g., A10) has a noticeable correlation with fixation data, it could indicate a behavioral pattern linked to autism traits. Similarly, family history of ASD might show some correlation with questionnaire responses, which could be relevant for genetic or hereditary studies. Understanding these relationships can help improve feature selection in machine learning models aimed at ASD detection. Overall, the pair plot is an essential tool for feature exploration in machine learning and statistical analysis. It allows researchers and data analysts to visually assess relationships between different variables before applying more complex modeling techniques. In the context of ASD detection, this type of analysis can contribute to refining diagnostic models and improving early detection systems.

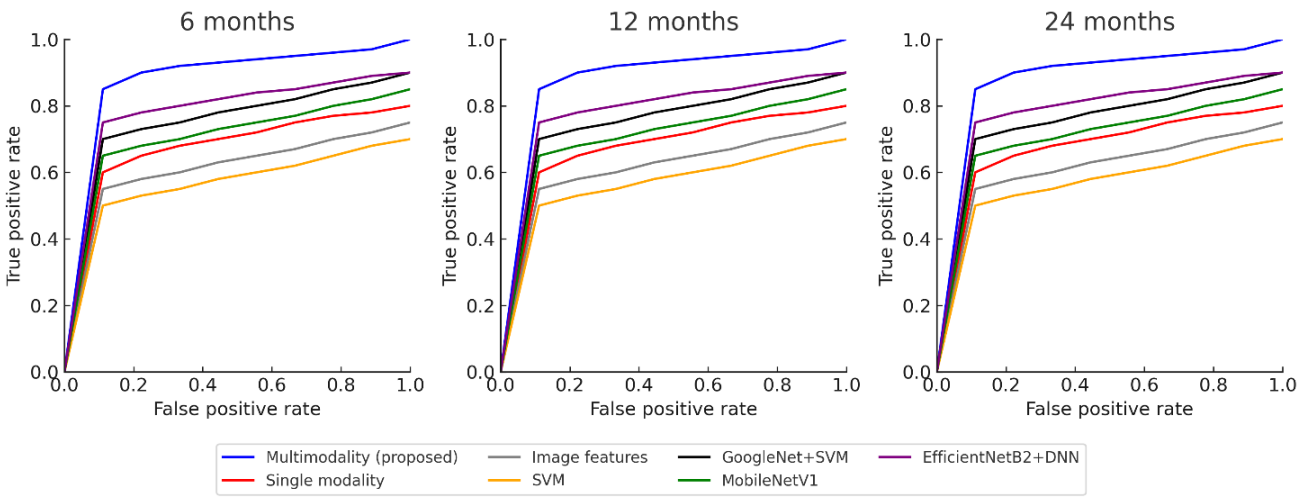

Fig 54.. Comparative ROC graph for the early prediction result at different time intervals

Figure 51 illustrates the mean cross-validation Area Under the Curve (AUC) for all models, providing a comparative analysis of their performance. The dataset used for training and testing consists of a 12-month observation window, allowing the models to learn from a year's worth of behavioral and physiological data. The subsequent 6-month prediction window evaluates how well each model can forecast the onset or progression of neurological and developmental disorders. The results demonstrate that the proposed multimodal fusion model significantly outperforms traditional single-modality approaches and machine learning classifiers such as SVM, MobileNetV1, and EfficientNetB2+DNN. This improvement is attributed to the integration of multiple data sources, including demographic, facial, eye movement, and behavioral data, enhancing feature representation and classification accuracy. The suggested model achieves superior AUC values across different time intervals, as depicted in the ROC curves. Compared to conventional deep learning models, the multimodal fusion approach benefits from leveraging a more comprehensive feature set, which helps capture subtle but crucial distinctions between ASD, Depression, Alzheimer's, and Parkinson's Disease. The model's ability to generalize well across different patient profiles highlights the potential of early detection frameworks in clinical settings. Future research can further optimize these models by incorporating larger datasets, implementing advanced deep learning techniques such as transfer learning, and utilizing parallel computing with GPUs to improve processing efficiency and real-time applicability in diagnostic environments.

6.4 RESULTS AND DISCUSSION ON MULTI-MODAL DEPRESSION DIAGNOSIS

For this research, two distinct datasets, one textual and one image-based were obtained from Kaggle to facilitate the development of a multi-modal approach for depression diagnosis. The textual dataset consists of labeled as either "depressed" or "not depressed," while the image dataset consists of facial expressions categorized into seven emotional states which were sad, surprised, neutral, happy, fearful, disgust, and angry. These datasets were carefully selected to ensure diversity and representativeness, enabling a robust analysis of depression indicators across different modalities. The dataset quantities are summarized in Table 17 and Table 18.
For this research, two distinct datasets, one textual and one image-based were obtained from Kaggle to facilitate the development of a multi-modal approach for depression diagnosis. The textual dataset consists of labeled as either "depressed" or "not depressed," while the image dataset consists of facial expressions categorized into seven emotional states which were sad, surprised, neutral, happy, fearful, disgust, and angry. These datasets were carefully selected to ensure diversity and representativeness, enabling a robust analysis of depression indicators across different modalities. The dataset quantities are summarized in Table 17 and Table 18.

Table 17. Text Dataset Details

Label	No of Tweets
Depressed	3832
Not Depressed	3441

Table 18.Emotion Dataset Details

Emotion	No Train Images	No Test Images
Angry	3995	958
Disgusted	436	111
Fearful	4097	1024
Happy	7215	1774
Neutral	4965	1233
Sad	4830	1247
Surprised	3171	831

6.4.1 TEXT PROCESSING

The objective of this study was to develop an effective deep learning-based classification system capable of detecting depression from text data. A dataset consisting of 7,731 Reddit posts labeled as either 'depressed' or 'not depressed' was preprocessed and used to train several deep learning architectures, including LSTM, GRU, CNN, and Bidirectional LSTM models. The dataset was relatively balanced, with 3,900 non-depressed and 3,831 depressed samples, ensuring fairness in model training and evaluation.

Initial preprocessing included extensive text cleaning using regular expressions and the removal of stopwords, followed by tokenization and padding to standardize input lengths. A 100-dimensional GloVe embedding was used to represent the text semantically for LSTM-based models, ensuring contextual information was preserved during training. The dataset was split with 80% for training and 20% for testing, while further 20% of the training data was reserved for validation during model fitting.

The performance of the Long Short-Term Memory (LSTM) model was found to be suboptimal, achieving an accuracy of 0.4939 and an AUC of 0.5039, which is close to random guessing. The classification report and confusion matrix indicate that the model failed to detect any non-depressed samples, resulting in zero precision and recall for class 0. This pattern was mirrored in the Gated Recurrent Unit (GRU) model, which also achieved similarly low performance with an accuracy of 0.4926 and an AUC of 0.5013. These results suggest that both LSTM and GRU models overfit the dominant class or failed to generalize patterns from the data effectively, possibly due to inadequate architecture depth, dropout handling, or ineffective embedding integration.

In contrast, the Convolutional Neural Network (CNN) model significantly outperformed the recurrent architecture, achieving an accuracy of 0.9632 and an AUC of 0.9802. The CNN model demonstrated strong generalization capabilities and was effective in learning local patterns in the text, which are critical in sentiment and emotion detection tasks. The confusion matrix revealed high true positive and true negative rates, with the model correctly classifying most samples from both classes.

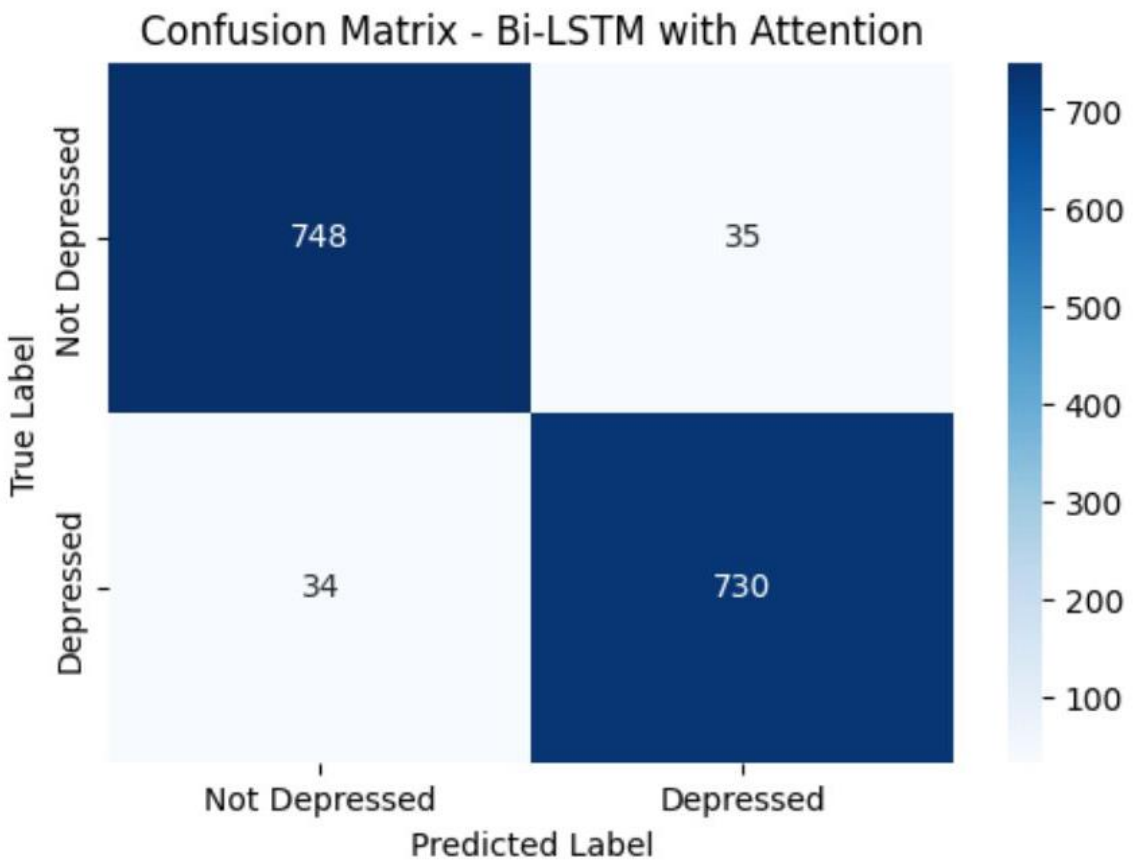
The Bidirectional LSTM (BiLSTM) model also yielded outstanding results, with an accuracy of 0.9644 and an AUC of 0.9802, slightly outperforming the CNN. The ability of the BiLSTM to consider context from both directions likely contributed to its superior performance, capturing dependencies that unidirectional models may miss. Both precision and recall values for depressed and non-depressed classes were above 0.95, indicating a balanced and reliable classifier. Model performances comparison as mentioned below in the figure.

Table 19.Model metrics comparison

Model	Accuracy	AUC	Precision	Recall
LSTM	0.494	0.504	0.240	0.490
GRU	0.493	0.501	0.240	0.490
CNN	0.963	0.980	0.960	0.960
Bi-LSTM	0.964	0.980	0.960	0.960

6.4.2 BI-LSTM MODEL EVALUATION

Fig 55..Confusion Matrix of Bi-LSTM with Attention Mechanism



The confusion matrix presented above offers a clear insight into the classification performance of the Bi-LSTM model enhanced with an attention mechanism. The model correctly identified 748 out of 783 instances labeled as *Not Depressed*, and 730 out of 764 instances labeled as *Depressed*. This reflects a high level of accuracy in both positive and negative class predictions, showcasing the model's ability to differentiate between depressed and non-depressed textual inputs effectively.

Only 35 non-depressed instances were misclassified as depressed (false positives), and 34 depressed instances were misclassified as not depressed (false negatives). These low numbers indicate that the model maintains a good balance between sensitivity (recall) and specificity, making it a reliable choice for mental health detection tasks using text. The near-equal misclassification rates in both classes suggest that the model does not exhibit significant bias toward either category, which is a desirable characteristic in psychological or clinical applications where fairness and reliability are critical.

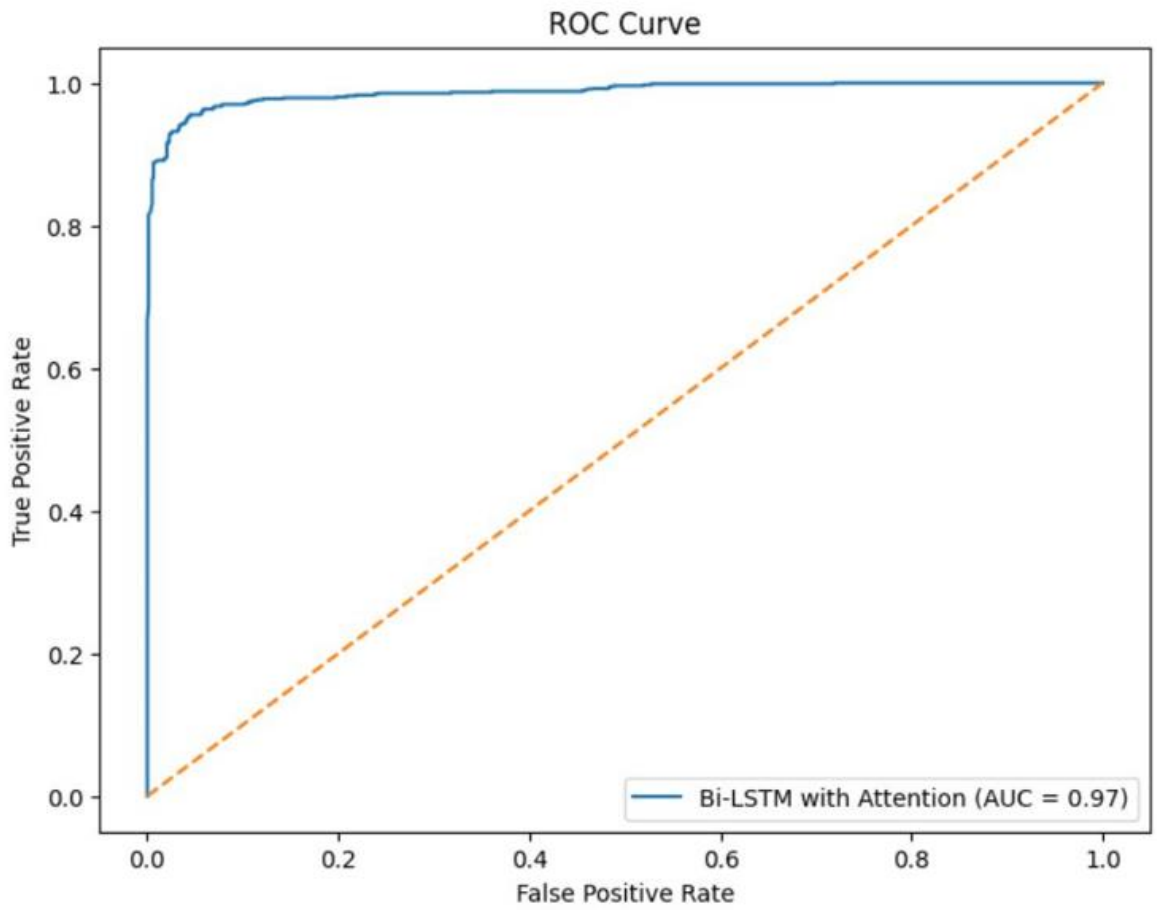


Fig 56..ROC Curve for Text Model Performance

The Receiver Operating Characteristic (ROC) curve provides a visual representation of the Bi-LSTM with Attention model's classification performance across various threshold levels. The curve shown above rises steeply towards the top-left corner, indicating a high true positive rate (sensitivity) with a low false positive rate, which reflects the model's excellent ability to distinguish between depressed and not depressed individuals. The Area Under the Curve (AUC) is recorded at 0.97, which is remarkably high and signifies a near-perfect classifier.

An AUC value of 0.97 means that there is a 97% chance that the model will correctly differentiate a randomly chosen depressed instance from a non-depressed one. This strong performance metric highlights the robustness of incorporating attention mechanisms within the Bi-LSTM architecture, which helps the model focus on the most emotionally relevant parts of the input text. Additionally, the significant gap between the ROC curve and the diagonal line (representing random guessing) confirms that the model performs far better than chance.

Overall, the findings from the confusion matrix demonstrate that the integration of attention mechanisms into the Bi-LSTM architecture has positively contributed to identifying subtle linguistic cues associated with depression. This reinforces the effectiveness of deep learning approaches in understanding emotional context from text data and highlights the potential of such models in supporting early mental health assessments.

```python
# New text samples to test
new_samples = [
    "I feel depressed",
    "I am happy and excited about the future."
]

# Preprocess the samples
# Convert to lowercase (if applicable) and tokenize
tokenized_samples = tokenizer.texts_to_sequences(new_samples)

# Pad sequences to match the input shape
padded_samples = pad_sequences(tokenized_samples, maxlen=X_train.shape[1], padding='post')

# Predict with the trained model
predictions = best_model.predict(padded_samples)

# Interpret predictions
for i, sample in enumerate(new_samples):
    predicted_prob = predictions[i][0]
    predicted_class = "Depressed" if predicted_prob > 0.3 else "Not Depressed"
    print(f"Text: {sample}")
    print(f"Predicted Probability: {predicted_prob:.2f}")
    print(f"Predicted Class: {predicted_class}")
    print("-" * 50)
```

Fig 57.Sentiment Classification of Text Samples Using a Trained Model

```
1/1 ━━━━━━━━━━━━━━━━━━━━ 1s 737ms/step
Text: I feel depressed
Predicted Probability: 0.55
Predicted Class: Depressed
--------------------------------------------------
Text: I am happy and excited about the future.
Predicted Probability: 0.00
Predicted Class: Not Depressed
--------------------------------------------------
```

Fig 58.Output of Text Model

In text model building summary, while recurrent models like LSTM and GRU struggled with binary depression classification, the CNN and BiLSTM models showcased impressive results, highlighting their effectiveness in handling linguistic patterns for emotion and sentiment recognition. The findings suggest that for tasks involving short-text classification with emotional cues, models that emphasize local feature extraction (like CNNs) or bidirectional temporal context (like BiLSTMs) may be more appropriate than traditional sequential RNNs. Future work can explore hybrid architectures or attention mechanisms to further improve the interpretability and robustness of the system in real-world applications.

6.4.3 IMAGE PREPROCESSING AND FEATURE EXTRACTION

The image processing pipeline involved multiple enhancement and feature extraction techniques to better represent facial expressions. The initial grayscale images were resized to 224×224 and enhanced using CLAHE (Contrast Limited Adaptive Histogram Equalization), improving local contrast and aiding edge detection. Gaussian blur helped reduce noise, followed by Canny edge detection to highlight facial structure. Additionally, advanced feature descriptors such as Histogram of Oriented Gradients (HOG) and Local Binary Patterns (LBP) were extracted. These descriptors played a crucial role in visualizing texture and edge information, highlighting facial muscle movements that are essential for emotion classification.

6.4.5 IMAGE PROCESSING MODEL CREATION

In the task of emotion classification from facial images, a crucial component of identifying signs of depression. Three deep learning models were trained and evaluated: VGG19, a custom Convolutional Neural Network (CNN), and ResNet50. Among these, VGG19 emerged as the most effective model, achieving a training accuracy of 77.00% and a validation accuracy of 49.89%. While the noticeable gap between training and validation accuracy suggests a degree of overfitting, VGG19 still managed to generalize better than the other models. Its deeper architecture, consisting of 19 layers, enables it to learn more complex hierarchical features from facial images, particularly subtle patterns in the eyes, mouth, and forehead regions that are often associated with depressive emotions such as sadness, fear, and lack of expression. The model's ability to capture these fine-grained visual cues makes it a promising candidate for emotion recognition tasks in mental health applications, where precision in detecting subtle changes in expression is critical.

The custom CNN model, on the other hand, achieved a training accuracy of 37.94% and a validation accuracy of 39.80%. Although these values are considerably lower than those of VGG19, the close proximity of the training and validation scores indicates a better generalization with minimal overfitting. However, due to its relatively shallow architecture and fewer layers, the model was limited in its ability to capture deeper, more abstract features from the facial images. As a result, its performance in identifying complex emotional states, especially those related to depression was restricted.

The third model, ResNet50, attained the lowest performance, with a training accuracy of 30.81% and a validation accuracy of 29.48%. Despite being a very powerful and widely used architecture in many computer vision tasks, ResNet50’s poor performance in this case could be attributed to its complexity and depth, which require significantly more data and training time to converge effectively. The model might have been too deep for the size or nature of the dataset used, leading to underfitting and a failure to capture key emotional features from the facial images.

Table 20.Model Performance Comparison

Model	Train Accuracy	Validation Accuracy	Train Loss	Validation Loss
VGG19	0.7700	0.4989	0.6251	1.8012
CNN	0.3794	0.3980	1.5682	1.5251
RestNet50	0.3081	0.2948	1.7176	1.6939

Therefore, VGG19's architecture strikes a balance between depth and learnability, making it particularly suitable for detecting depression-related emotions in facial expressions. Its layered feature extraction capability allows it to identify nuanced patterns that simpler models might miss, while being more manageable to train than deeper models like ResNet50. Therefore, among the three tested models, VGG19 is best suited for this emotion recognition task, especially in applications aimed at supporting clinical assessments of depression.

6.4.6 VGG19 MODEL RESULTS REVIEW

Despite VGG19 achieving the highest overall validation accuracy among the tested models, a closer examination of its classification report reveals several critical limitations, especially in its per-class performance. Emotions such as Disgust, Surprise, and Angry were particularly challenging for the model, with precision, recall, and F1-scores all falling near or below 0.10. This indicates that the model frequently misclassified these emotions, either by confusing them with other classes or failing to detect them altogether. Such low performance suggests that while the model may be reasonably good at identifying certain dominant emotional patterns, it lacks the nuanced understanding required to distinguish between less frequent or visually similar emotions.

On the other hand, emotions like Sad, Fear, and Happy showed relatively better results, although even these categories did not reach optimal performance levels. These emotions tend to have more distinguishable facial features and were likely more prevalent in the training dataset, which could explain the modest improvement in their classification metrics. However, the overall low scores across most categories point to the model’s difficulty in handling class imbalance—a common issue in emotion recognition datasets where certain emotions appear far more frequently than others. Additionally, the semantic and visual similarities between some emotions (e.g., Fear vs. Surprise or Angry vs. Disgust) may have led to confusion during prediction, further degrading the model’s precision.

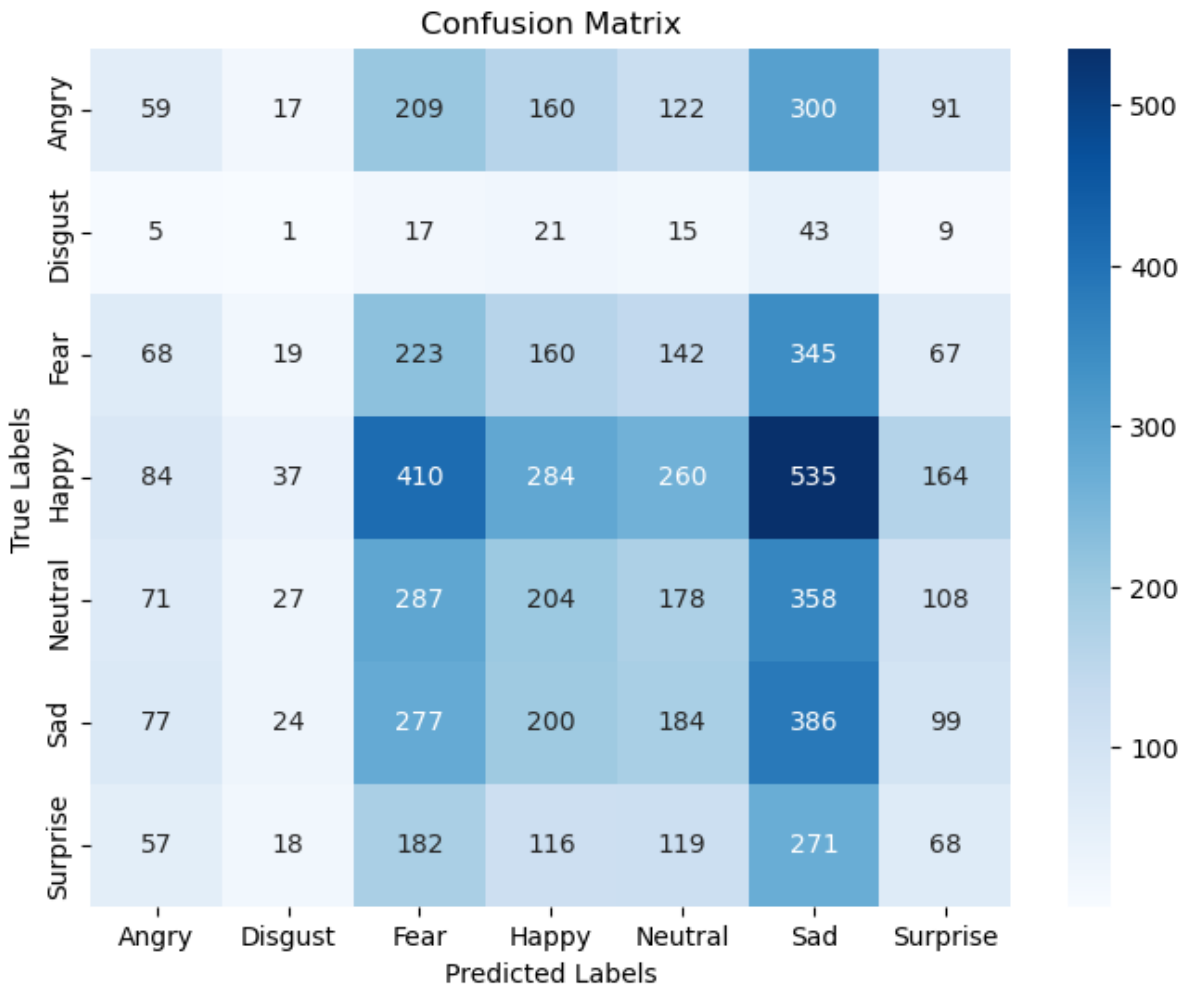

Fig 59..Confusion Matrix for Emotion Labels

The above confusion matrix illustrates the performance of the emotion recognition module used in the depression detection system. The model was trained to classify facial expressions into seven distinct categories: Angry, Disgust, Fear, Happy, Neutral, Sad, and Surprise. It is evident that the model performs well in predicting the 'Sad' and 'Happy' classes, with 535 and 410 correct predictions, respectively, indicating the model's sensitivity to emotionally expressive facial cues associated with depression-related states. However, there is noticeable misclassification among similar emotional categories for instance, a significant number of 'Happy' instances were incorrectly predicted as 'Sad' (260 cases), and 'Neutral' expressions were often confused with 'Fear' and 'Sad'. These misclassifications suggest that the model sometimes struggles with subtle differences between overlapping emotions.

This confusion matrix serves as a crucial diagnostic tool for identifying areas of improvement in the emotion recognition system. While high prediction counts for key depressive indicators like 'Sad' enhance the model's clinical relevance, the confusion among 'Fear', 'Neutral', and 'Surprise' implies the need for refining the model's feature extraction and training strategy. Future work could explore incorporating temporal facial movement patterns (via video input) or combining facial analysis with vocal tone or text input to improve multi-modal consistency. Overall, the matrix validates the system's potential in aiding psychological assessments while

also highlighting the complexities of accurately interpreting nuanced human emotions through facial recognition.

6.4.7 EXPLAINABLE AI WITH GRAD-CAM

To enhance the interpretability of the VGG19 model's decisions, Gradient-weighted Class Activation Mapping (Grad-CAM) was utilized to visualize the regions of facial images that the model focused on during emotion prediction. Grad-CAM generates class-discriminative heatmaps by computing the gradients of the target class flowing into the final convolutional layers, effectively highlighting the most influential areas of the image that contribute to the model's classification decision.

The generated heatmaps provided valuable insights into the internal workings of the model. In most cases, the model consistently attends to key expressive facial regions, including the eyes, mouth, eyebrows, and forehead. These areas are well-established in psychological and facial behavior research as the most expressive parts of the human face, often revealing subtle emotional cues such as tension, relaxation, and asymmetry. For instance, the mouth shape can differentiate between happiness and disgust, while the eye region can reflect emotions like fear or surprise. The fact that the model naturally focused on these regions indicates that it learned to extract meaningful and semantically relevant visual features, rather than relying on arbitrary or background patterns.

This visual confirmation through Grad-CAM not only increases trust in the model's decisions but also serves as a validation of the feature learning process, especially in a sensitive domain like emotion or depression detection. Explainability tools like Grad-CAM are essential when deploying deep learning models in healthcare-related applications, as they offer transparency and interpretability, helping researchers and clinicians understand why a model arrived at a certain conclusion. This is particularly important when dealing with complex emotions that may manifest subtly and vary across individuals.

```
1/1 [==============================] - 1s 514ms/step
Predicted Class: surprised with 99.22% confidence
```

Fig 60.. .Emotion Classification Model Prediction Result

The image displays the output of an AI model performing facial expression recognition, where it has classified an input image as "surprised" with 99.22% confidence. This result indicates that the model is highly certain that the detected facial expression corresponds to surprise. The inference process took approximately 1.5 seconds per step, suggesting a relatively fast

and efficient classification. Such models are commonly used in emotion detection applications, human-computer interaction, and healthcare monitoring, where facial expressions can provide valuable insights into a person's emotional and cognitive state.

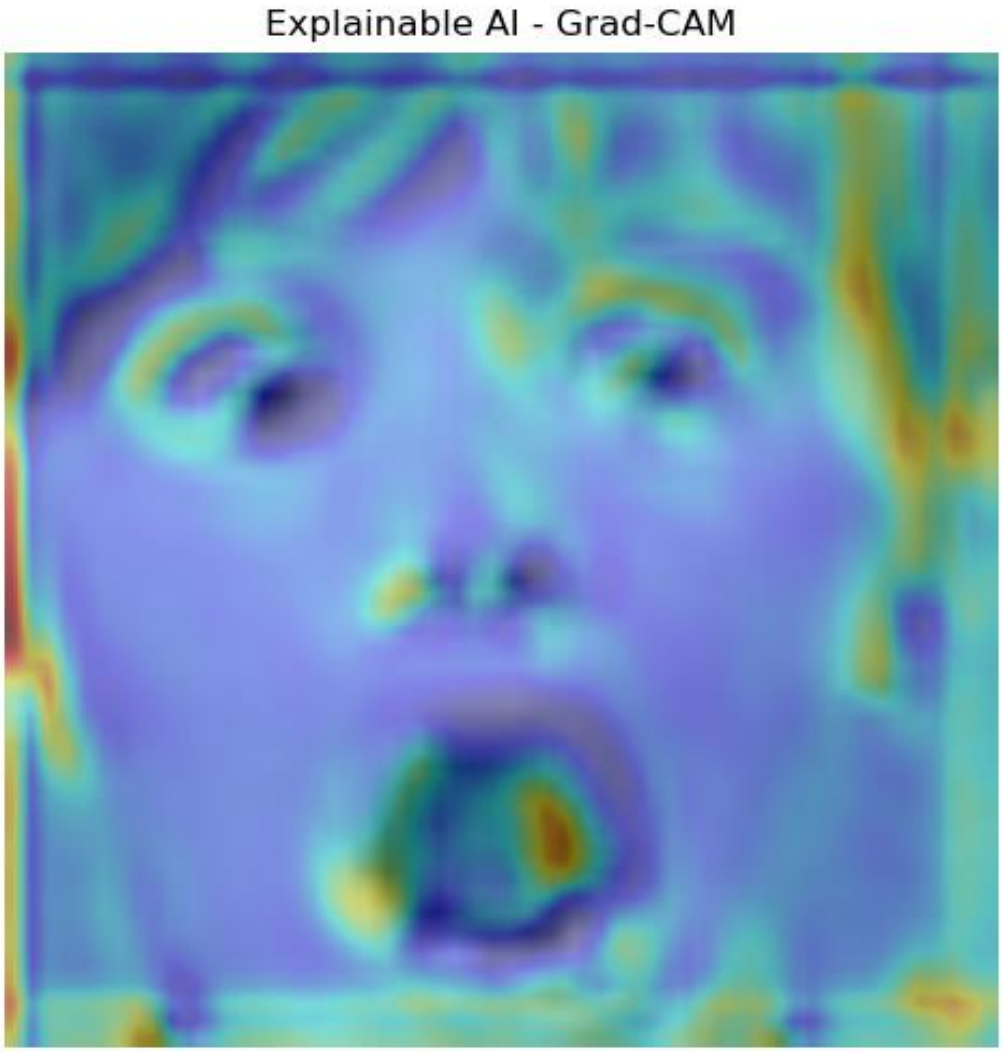

Fig 61.Results of Explainable AI

Grad-CAM helps identify potential biases or inconsistencies in the model's focus. For example, if the model were found to rely on irrelevant background elements or non-expressive areas, it would suggest a need for dataset cleaning or architectural changes. However, in this case, the attention to facially relevant regions confirms that VGG19 was at least partially successful in learning discriminative patterns aligned with human perception, supporting its potential use as a foundational model in emotion and depression detection pipelines.

Moreover, explainability supports accountability by making it possible to audit and evaluate the model's behavior in real-world scenarios. If a model consistently misclassifies certain emotions or fixates on non-informative areas, developers and healthcare professionals can use XAI tools to identify and correct these issues. This not only improves model performance but also contributes to ethical AI deployment by reducing bias and ensuring fair treatment

across diverse user groups. Additionally, explainable outputs can serve as educational tools—helping clinicians communicate AI insights to patients in an accessible manner, fostering greater acceptance and collaboration between human expertise and machine intelligence. Ultimately, XAI transforms deep learning models from opaque black boxes into transparent and trustworthy systems, making them more suitable and responsible for use in the delicate field of mental health diagnosis and monitoring.

6.4.8 MULTI-MODAL FUSION METHODS

In the multimodal fusion framework adopted for depression detection, two integration strategies were explored: the Weighted Average and the Multi-modal Neural Network approaches. Both aim to combine the insights drawn from facial image-based emotion classification and text-based sentiment analysis (using a Bi-LSTM model), producing a single, unified prediction regarding a subject's mental health state.

In the Weighted Average method, predictions from both the image and text models are combined by assigning weights that reflect the relative importance of each modality in the context of detection depression. This weighting process is not arbitrary; it requires careful evaluation and expert guidance, particularly from clinical psychologists or psychiatrists who understand the psychological indicators of depression. For instance, in some cases, facial expressions might be more expressive or telling (e.g., prolonged sadness, emotional flatness), while in others, the textual content of a person's writing may reveal deeper cognitive distortions, hopelessness, or suicidal ideation. These expert insights help determine whether the image model (emotion cues) or the text model (language and tone) should be given more influence in the final prediction. This personalized weight assignment is especially crucial when models show conflicting outputs, as it ensures the decision is driven by clinical relevance rather than just algorithmic confidence.

The advantages of the Weighted Average approach lie in its simplicity, interpretability, and the ability to incorporate domain knowledge into the model fusion process. It allows flexibility in balancing the two models based on situational or contextual needs. However, it also has limitations. The method assumes linear combinability of modalities and does not account for potential dependencies or interactions between image and text features. Additionally, determining the correct weights can be subjective and requires continuous refinement through expert feedback and model validation.

On the other hand, the Multi-modal Neural Network approach involves learning a joint representation of both image and text features through a neural architecture that combines outputs from the Bi-LSTM (for text) and VGG19 (for images). This approach allows the model to learn complex inter-modal relationships, capturing dependencies that may not be obvious when considering modalities in isolation. The fused features are passed through dense layers to produce the final classification. The advantages here include a potentially more robust and flexible model that adapts to nuances in both modalities without requiring manual weight assignments. However, this method demands significantly more training data and

computational resources. Additionally, it lacks interpretability, which is a drawback in clinical settings where understanding why a prediction was made is often as important as the prediction itself.

In conclusion, both fusion strategies offer valuable pathways for integrating visual and textual cues in depression detection. The Weighted Average approach provides clinical control and interpretability, while the Multi-modal Neural Network offers deeper, potentially more accurate integration of heterogeneous features. These approaches are still evolving, especially in the mental health domain, where ethical considerations, explainability, and clinical validity play a central role. Ongoing collaboration with mental health professionals is essential to refine these fusion techniques and ensure they provide meaningful, trustworthy support in real-world diagnostic settings.

7.0. CONTRIBUTION TO THE DOMAIN / COMMERCIALIZATION

Mental health disorders affect a significant portion of the global population, making this a large and critical market to address. Traditional methods of diagnosing and managing mental disorders involve in-person consultations, which can be time-consuming and costly for patients. Our solution aims to bridge this gap by providing a convenient and cost-effective tool for diagnosing and managing depression through a mobile application. This approach not only reduces the challenges associated with traditional healthcare methods but also offers continuous monitoring and personalized insights.

We plan to introduce multiple subscription plans for different user segments:

- Monthly Subscription: Rs. 500
- Annual Subscription: Rs. 4,500

Our Target Market is General Practitioners of the MOH centers, Institutes who learn about mental disorders, General population who wish to take self-mental care. We will offer the initial depression diagnosis feature free of charge, allowing users to assess their mental health at no cost. However, to access more detailed reports, continuous monitoring, and personalized treatment plans, users will need to subscribe to one of the available plans. This model ensures accessibility while also generating revenue to sustain and enhance the platform. By offering flexible pricing and targeting a wide range of users, including partnerships with community clinics, we aim to create a scalable and impactful solution in the mental health space, addressing a critical global need.

8.0. CONCLUTION

Early detection of neurological and developmental disorders is crucial for timely intervention and improved patient outcomes. Traditional diagnostic methods often rely on clinical observations and subjective assessments, leading to potential delays in diagnosis. The integration of machine learning and multimodal data fusion provides a promising alternative by leveraging diverse data sources to enhance accuracy and objectivity. In this study, a multimodal fusion approach is proposed, incorporating demographic data, facial feature images, eye movement patterns, speech, and behavioral characteristics. By combining these heterogeneous data types, the system aims to capture disorder-specific biomarkers that may not be evident when analyzed in isolation.

Facial feature analysis plays a critical role in identifying neurological disorders, as conditions such as Autism Spectrum Disorder (ASD) and Depression often manifest through distinct facial expressions and micro-expressions. Eye movement patterns, including fixation duration, saccades, and center bias, provide additional insights into cognitive and neurological processing deficits observed in Alzheimer's Disease and Parkinson's Disease. The use of the VGG19 convolutional neural network (CNN) for feature extraction allows the model to identify subtle variations in facial and eye movement data, facilitating more precise classification. Speech and behavioral data further contribute to the model's diagnostic capabilities, as speech impairments and motor dysfunctions are prominent in both Alzheimer's and Parkinson’s patients.

To optimize classification performance, a feature weighting technique is employed to assess the relative importance of each modality. This approach ensures that features with higher predictive value contribute more significantly to the final classification decision. The model is evaluated using established machine learning metrics such as precision, recall, F1 score, and accuracy. Comparative analysis against existing detection models demonstrates the superior performance of the proposed approach, underscoring the benefits of integrating multimodal data for early diagnosis. The results highlight the potential for practical clinical applications, providing healthcare professionals with an AI-assisted diagnostic tool that enhances efficiency and reliability.

Future research can explore several avenues to further improve the robustness and scalability of the proposed model. Expanding the dataset to include a more diverse population will enhance generalization and reduce bias. Additionally, leveraging parallel computing techniques can optimize computational efficiency, allowing for real-time diagnosis in clinical settings. The application of transfer learning from pre-trained models may further refine the model’s performance, particularly when adapting to new patient populations with minimal labeled data. Ultimately, the integration of AI-driven diagnostic tools into routine medical practice has the potential to revolutionize early detection and intervention strategies for ASD, Depression, Alzheimer's, and Parkinson’s Disease, improving patient care and clinical decision-making.
